BOX 23-4 Factors Not Affecting Prognosis in Patients with Metastasectomy

- Age
- Sex
- Unilateral versus bilateral disease
- Wedge resection versus formal lobectomy

in a study by the National Cancer Institute in which patients underwent re-resection for soft tissue sarcomas, no difference in the actuarial 5-year survival was found in those undergoing one, two, and even three resections for recurrence.⁷³ To appropriately choose patients for repeat resection, it is important to use preoperative selection criteria that are similar to those used for the initial resection. This ensures the absence of disseminated disease and the ability of a given patient to tolerate the proposed procedure.

SPECIFIC SECONDARY LUNG TUMORS

Soft Tissue Sarcoma

Soft tissue sarcomas consist of a heterogeneous group of nonossifying malignant neoplasms derived from mesenchymal connective tissue. In a 1997 report from the International Pulmonary Metastases Registry, soft tissue sarcomas were the most common type of pulmonary metastases resected, and they accounted for 42% of all

patients undergoing metastasectomy.⁷⁵ Unfortunately, only 50% of patients with lung metastases from sarcoma are operative candidates, and of those, 80% undergo complete resection. It is from that 80% that the 5-year survival rates of 20% to 40% are obtained.⁷⁶ Soft tissue sarcomas typically respond poorly to systemic chemotherapy, making surgery the only potentially curative treatment option. However, in the absence of a randomized trial, it is impossible to know whether these results reflect careful patient selection and favorable biology rather than a specific benefit of surgery.

Patients with extremity soft tissue sarcomas tend to develop pulmonary metastases more frequently than those with sarcomas at other sites.⁷⁷ Gadd and coworkers analyzed histopathologic findings of soft tissue extremity sarcomas and their relationship to pulmonary metastases.⁷⁶ The probability of pulmonary metastases developing from a soft tissue sarcoma is influenced by histopathologic factors such as grade, size, and location of the primary tumor. Patients with spindle cell sarcoma had the highest incidence of pulmonary metastases, whereas those with liposarcomas had the lowest incidence.

Regardless of histology, primary and repeat metastasectomy has been associated with improved long-term survival. A study from Memorial Sloan-Kettering focusing on 719 patients with sarcoma who had pulmonary metastases showed a 3-year survival rate of 46% for patients undergoing resection, compared with 17% for those treated nonsurgically.⁷⁸ Favorable prognostic indicators include completeness of resection, disease-free interval, tumor doubling time greater than 40 days, number of nodules (four or fewer), grade, tumor histology, radicality of resection, and age.^{66,78-80}

Pulmonary re-recurrence after complete resection of metastatic soft tissue sarcomas has been reported to occur in 45% to 83% of patients, and the lungs represent the main reason for ultimate treatment failure in up to 80% of patients.⁸¹ Five-year survival rate of 36% after re-resection of soft tissue sarcomas has been reported.⁸² Patients whose metastases cannot be completely resected, those with large metastases (>2 cm), and those with high-grade primary tumor pathology tend to have worse outcomes.⁸³

Osteosarcoma (Osteogenic Sarcoma)

Like soft tissue sarcomas, osteosarcoma has a strong predilection for metastasis to the lung. In addition, the lesions themselves are frequently multiple and often recur despite resection. Consequently, pulmonary involvement is responsible for most deaths in patients with this disease. Approximately 10% to 20% of patients have distant metastases on initial evaluation and, as with other histologies, CT of the chest is the imaging modality of choice for detection.

Before the introduction of chemotherapy, the overall survival from osteogenic sarcoma was only 10% to 20%.^{70,83} In the early 1970s, however, the use of chemotherapy, especially high-dose methotrexate, substantially improved outcomes.⁸⁴ Later, with the introduction of multimodality therapy, chemotherapy (doxorubicin, high-dose cyclophosphamide, and cisplatin) combined

with resection improved 5-year survival rates to 32% to 40%.^{14,85} In some cases, treatment resulted in cure. As a consequence of these improved results early in the history of metastasectomy, a more aggressive approach toward resection of pulmonary metastases developed. These favorable outcomes in selected patients treated aggressively with multimodality therapy, including pulmonary metastasectomy, have been duplicated by others in recent years.^{86,87} Despite the survival advantage imparted by surgical resection in osteogenic carcinoma, tumor recurs in 50% of patients within 1 year. Eventually, 85% of these patients relapse with recurrent pulmonary disease, despite adequate removal of the primary tumor and no earlier evidence of gross secondary disease. Resection of these recurrences is indicated if feasible, as numerous studies have demonstrated improved survival.^{29,88} If the patient is not a surgical candidate, radiotherapy or radiofrequency ablation may be an option.

No prognostic factors, except complete resection, have consistently been associated with improved survival after metastasectomy. A number of studies have looked at the aforementioned characteristics (age, sex, location, doubling time, disease-free survival, number of nodules, resectability) but found that few consistent conclusions could be drawn. In most studies, a worse outcome correlated with an increased number of nodules.^{14,89} All studies conclude that complete surgical resection is indicated, and when resectability was studied, incomplete resection was always associated with a worse outcome.^{14,90,91} In addition, the location of the primary lesion has been associated with worse prognosis in the case of pelvic and vertebral tumors.⁹²

Colorectal Cancer

The lung and liver are the most common sites of metastatic disease in colorectal cancer. Marked improvements in the survival of patients with metastatic colorectal cancer have been seen in the past decade, which is attributed mostly to several new drugs. Despite this, surgical resection is widely accepted as having a prominent role in the treatment of patients with synchronous or metachronous metastatic disease in the lungs. Because of the increasing number of active agents at the oncologist's disposal, surgical resection and its timing need to be planned carefully in a multidisciplinary fashion.

The evidence of survival benefit continues to be limited due to a lack of prospective data. However, multiple studies of pulmonary resection of metastatic colorectal carcinoma have demonstrated that the survival in selected patients at 5 years ranges from 27% to 61%. Prognostic factors associated with improved prognosis in patients with pulmonary metastases from colorectal cancer include primary tumor stage and completeness of the resection. Other prognostic factors may include number of pulmonary metastases, pre-thoracotomy carcinoembryonic antigen (CEA) serum level, and presence of lymph node metastases.⁹³⁻⁹⁹ Even in the presence of synchronous and metachronous colorectal metastases to the lung and liver, surgical management of both can result in long-term survival, albeit less favorable than those with more limited metastatic disease. Barlow and colleagues observed a

median survival of 44 months after combined liver and lung resection.¹⁰⁰ Gonzalez and colleagues observed a median disease-free survival of 13 months after pulmonary metastasectomy in patients who had previously undergone liver resection for liver metastasis.¹⁰¹

These retrospective studies have formed the rationale for the recommendation of surgical resection in patients with colorectal cancer metastases to the lung, but the perception of selection bias continues to bring into question whether this practice is truly improving survival. A prospective randomized trial (PulMiCC) is currently under way in the United Kingdom to attempt to answer this question.¹⁰²

Breast Carcinoma

Pulmonary involvement in breast cancer is most commonly associated with widespread disease, such that a thorough search for extrathoracic disease is warranted before considering metastasectomy. In a series of 5143 patients with breast cancer, Staren and coworkers reported lung metastases in 284 patients, and only 1% of these had metastatic disease confined to the lung.¹⁰³ They observed a significant 5-year survival advantage for patients who underwent metastasectomy (36% versus 11%). Factors conferring a more favorable prognosis include estrogen and progesterone receptor (ER/PR) status and a complete resection.^{104,105} Meimarakis et al recently published their favorable results of lung metastasectomy in breast cancer, including statistically significant overall survival in surgical patients in a matched pair analysis when matched for age and tumor-nodes-metastasis (TNM) status of original tumor.¹⁰⁶

In addition to a possible therapeutic benefit, resection of a breast cancer metastasis offers reassessment of molecular markers (ER, PR, and HER2) because of the 5% to 30% discordance rate between receptor status of primary lesions when compared with subsequent metastasis. These changes can dramatically affect the type of adjuvant therapy offered.¹⁰⁷

Head and Neck Carcinoma

Head and neck carcinomas most commonly spread through local lymphatics. The lung is among the more common sites of distant spread, followed by bone and liver. Patients with head and neck cancer and a history of frequent tobacco use are at risk for other foregut malignancies. A solitary nodule in a patient with a history of head and neck cancer has a greater chance of being a lung primary tumor and should be treated as such. Five-year survival rates after metastasectomy for head and neck cancers range from 29% to 59%.¹⁰⁸ Shiono et al recently reported overall 5-year survival following pulmonary metastasectomy of 26.5%, with male gender and oral cavity primary tumor associated with very poor outcomes.¹⁰⁹

Renal Cell Carcinoma

The lung is a frequent site of renal cell metastases, with prevalence rates as high as 72% to 76% in autopsy

studies.^{110,111} Over the past decade, tyrosine kinase inhibitors such as sorafenib and sunitinib have been shown to delay disease progression in patients with metastatic renal cell carcinoma, but surgical resection in selected patients continues to demonstrate a survival benefit in retrospective series and even cure, as first reported by Barney and Churchill in 1939.¹¹² Several retrospective studies have been published demonstrating the beneficial effect of resecting renal cell cancer metastases to the lung, with reported 5-year survival rates ranging from 20% to 50%. Han and colleagues reported that patients with evidence of disease in multiple organs fare significantly worse than those with metastatic disease limited to the lungs.¹¹³ Patients with a solitary renal metastasis fare best, with a 5-year survival of up to 54%.¹¹⁴ Assouad and colleagues observed that 5-year survival was significantly affected by the size of the largest metastasis and by mediastinal lymph node involvement.¹¹⁵ Synchronous metastases, greater than six metastases, absence of regional and mediastinal nodes, and resectability have been identified as being important prognostic factors.^{104,116} Results of long-term follow-up studies support an aggressive surgical approach in patients with renal carcinoma metastases to the lungs.^{22,117}

Germ Cell Tumors

Germ cell tumors account for only 1% of all cancers, but they are the most common malignancy in male patients between the ages of 15 and 35 years. Most germ cell tumors are highly responsive to chemotherapy and even patients with metastatic disease have an excellent prognosis. Most patients with metastatic testicular tumors demonstrate a complete clinical remission after treatment with chemotherapy. Surgical intervention for pulmonary metastases from germ cell tumors is primarily reserved for evaluation of a residual mass after chemotherapy, particularly in nonseminomatous types. In these cases, resection of the metastatic sites of residual disease results in removal of chemotherapy-resistant elements as well as identification of residual viable cancer that may require additional chemotherapy.

In the 25% to 30% of patients with a residual mass after chemotherapy for nonseminomatous germ cell tumors, it is difficult to differentiate necrosis from a mature teratoma or persistent tumor. Cagini and coworkers reported on a series of 144 patients who underwent resection of a residual mass after chemotherapy for metastatic germ cell tumors.¹¹⁸ Viable malignant elements were found in 44 patients, and 63 patients were found to have a differentiated teratoma. An overall 5-year survival rate of 77% was observed, with a worse rate (51%) in patients with malignant teratomatous elements. Special considerations in this group include prior exposure to bleomycin, which results in increased risk of pulmonary complications following surgery.¹¹⁹

Gynecologic Tumors

The lung represents the most common organ involved in uterine cancer spread, with isolated pulmonary metastases observed in approximately 6% of patients.¹²⁰

Pulmonary metastasectomy for uterine cancer is associated with a 5-year survival rate of approximately 50% in well-selected patients.¹²¹ Anderson and colleagues observed improved median survival in patients undergoing pulmonary metastasectomy for adenocarcinomas (46 months) compared with leiomyosarcomas (25 months), although median survival reported by Clavero and colleagues was similar.^{120,122} Completeness of resection, longer disease-free interval, and three or fewer metastases have been associated with an improved survival rate in this patient population.¹²³ Additionally, ER/PR status of pulmonary metastases is significant with cancers of uterine origin, as patients with positive ER/PR receptors have an 80% response rate and average survival rates of up to 33 months.¹²⁴

Most patients with ovarian cancer metastatic to the lung have malignant effusions.¹²⁵ Disease confined to the lung amenable to metastasectomy is exceedingly rare.

Melanoma

Patients with metastatic melanoma often present with widely disseminated disease, and isolated pulmonary metastases are rare. The lungs are the second most common site of metastases in patients with melanoma, with a prevalence of between 12% and 36%.^{126,127} The annual probability of developing pulmonary metastases increases progressively from 10% at 5 years to 17% at 15 years.

An aggressive surgical approach to pulmonary metastatic disease from melanoma is warranted as long as a complete metastasectomy can be performed. Evidence for this is based in part on studies from Harpole and colleagues and Taft and coworkers, who reported 5-year survival rates of 20% and 27%, respectively, in patients undergoing pulmonary metastasectomy, versus 4% and 3%, respectively, in patients treated medically.^{128,129}

If a complete resection cannot be performed, little or no benefit is provided in terms of prolonging patient survival. Additional factors influencing survival include disease-free interval less than 5 years, prior chemotherapy, nodular histology, the presence of more than two pulmonary nodules, and positive lymph nodes.^{128,130}

Endocrine Tumors

The lungs represent an uncommon site of metastases for malignant endocrine tumors. A select group of patients with slow-growing endocrine tumors, including carcinoids, well-differentiated thyroid cancers, and parathyroid cancers, may benefit from resection of their metastases. In a retrospective review, Khan and coworkers reported shorter survival in patients with positive mediastinal lymph nodes at the time of resection and a shorter disease-free interval.¹³¹ Occasionally, metastases may be resected to alleviate symptoms of hormone production.^{132,133}

Other Tumors

Small retrospective series have demonstrated encouraging survival rates when compared with historical data when

lung metastases have been identified for other histologies. These included hepatocellular carcinoma,¹³⁴ gastric cancer,¹³⁵ and pancreatic adenocarcinoma.^{136,137} In fact, in addition to considering disease-free interval, limited sites of disease, complete resectability, and low anticipated morbidity, surgeons should also consider resection of suspected lung metastasis for patients with cancer.

ALTERNATIVE TREATMENT OPTIONS

In patients with lung metastases deemed appropriate for locoregional therapy, several options are available to patients who are medically inoperable or who decline surgery. The data for these therapies are substantially limited compared with the data for surgery, and no randomized data exist. Options include stereotactic body radiation therapy, radiofrequency ablation, and cryoablation.

Stereotactic body radiation therapy (SBRT) is a technique that uses localized radiation treatments delivered in a limited number of fractions. The end result in the lung is high-dose radiation to a small area of lung tissue, minimizing damage to adjacent lung and mediastinal structures. Successful use of SBRT to treat intracranial and skull base tumors led to applications in other regions, including the lung. Side effects include chest wall pain and rib fractures when treating lesions abutting the pleura and lung toxicity, because of airway necrosis, when treating central lesions. Local control rates (defined as stabilization or decrease in size of the treated lesion) in oligometastatic disease have been reported in the 87% to 100% range.¹³⁸

Radiofrequency ablation (RFA) is a thermal energy delivery system that applies an alternating current through a needle electrode into a tissue. The result of energy delivery is coagulative necrosis and tissue destruction in the vicinity of the probe. Lung parenchyma is thought to be a good place to use RFA because pulmonary tissue surrounding solid tumors acts as a thermal insulator, allowing energy to focus on the area of the solid tumor.¹³⁹ Lesions can be approached percutaneously with CT guidance or through an incision in the operating suite.

Inclusion criteria for RFA are lesions no larger than 5 cm in diameter, inoperable non-small cell lung cancer, and no more than four secondary lesions in both lungs. The feasibility of RFA depends on factors such as the presence of an "access window" and proximity to hilar structures. Complications of RFA include pneumothorax requiring intervention (30%), pleural effusion, hyperpyrexia, infection, and hemorrhage. Chua and colleagues reported their experience using RFA for lung tumors (73% were colorectal cancer metastases) in 148 patients who were not candidates for surgical resection. They found 46% had a complete response, 39% had stable disease, 16% had progressive disease, and median progression-free survival was 11 months.¹⁴⁰

PALLIATIVE THERAPY

Palliative therapies include laser ablation of airway lesions, tracheobronchial photodynamic therapy (PDT),

radiation modalities, and airway stenting. Hemoptysis resulting from pulmonary metastases is usually controlled with external beam radiation, laser ablation, or PDT. The neodymium:yttrium-aluminum garnet laser provides effective coagulation and tumor necrosis, and it is helpful in the removal of endobronchial tumors causing obstruction. It can be used effectively via a flexible or rigid endoscope. PDT has been shown to prolong airway patency and can be used as the primary treatment modality or in conjunction with the laser. Finally, airway stenting is frequently used either alone or in conjunction with other palliative therapies to improve patient quality of life.

CONCLUSIONS

Currently, metastasectomy is the treatment of choice in appropriately selected patients with metastatic disease to the lungs for most neoplastic histologies. Selection guidelines now available are useful in determining which patients benefit from metastasectomy. The role of pulmonary metastasectomy is changing as more effective systemic chemotherapy treatment regimens become available, and more experience is obtained with less invasive techniques. Controlled clinical trials will be needed to aid the clinician in selecting the most appropriate treatment for each individual patient.

Asphyxiating Thoracic Dystrophy (Jeune Disease)

Spondylothoracic Dysplasia (Jarcho-Levin Syndrome)

A great variety of congenital abnormalities of the chest wall occur. Their physiologic implications are also quite varied and span the spectrum from the rare entities of ectopia cordis and asphyxiating thoracic dystrophy, which are often lethal, to the much more common pectus excavatum and pectus carinatum with their limited physiologic impact. In this chapter anterior thoracic deformities will be considered in five categories: pectus excavatum, pectus carinatum, Poland syndrome, sternal defects (including ectopia cordis), and miscellaneous conditions (including asphyxiating thoracic dystrophy [Jeune syndrome]).

PECTUS EXCAVATUM

Pectus excavatum is the most frequent anterior chest wall deformity. The central depression of the chest is produced by posterior angulation of the sternum and the costal cartilages. The first and second costal cartilages and the manubrium are usually in a normal position (Fig. 24-1), but the lower costal cartilages, which insert into the sternum and the body of the sternum, are depressed.

The most anterior segment of the ossified portion of the ribs may also be curved posteriorly in older adolescents and adults. The extent of sternal and cartilaginous deformity is variable. Numerous methods of grading these deformities have been proposed by Hümmer and Willital,¹ Oelsnitz,² Welch,³ Haller and associates,⁴ and others, but none has been universally accepted. Asymmetry of the depression is often present. The right side is frequently more depressed than the left, and the sternum may be rotated as well. A system to quantify the asymmetry based on computed tomography (CT) scan of the chest has been reported.⁵ Many children with pectus excavatum have a characteristic physique with a broad thin chest, dorsal lordosis, “hook shoulder” deformity, costal flaring, and poor posture.

Pectus excavatum is present at birth or within the first year of life in most affected children (86%), as shown in Figure 24-2. The deformity rarely resolves with increasing age, and it may worsen during the period of rapid growth in adolescence. Waters and associates identified scoliosis in 26% of 508 patients with pectus excavatum. Hence, it is important that all patients with pectus deformities are evaluated clinically for scoliosis. Asymmetrical

FIGURE 24-1 ■ A 16½-year-old boy with a symmetrical pectus excavatum deformity. Note that the depression extends to the sternal notch.

FIGURE 24-2 ■ Age at appearance of pectus excavatum deformity in 704 infants and children. Note the large proportion identified at birth or within the first year of life and the predominance of males with this deformity. (From Shamberger RC, Welch, KJ: Surgical repair of pectus excavatum. *J Pediatr Surg* 23:615, 1988. With permission.)

pectus excavatum with a deep right gutter and sternal rotation often is accompanied by scoliosis.⁶ Congenital heart disease was identified in 1.5% of infants and children undergoing chest wall correction at Boston Children's Hospital (Table 24-1).⁷ The frequency of chest wall deformities among all patients with congenital heart disease evaluated at this institution was only 0.17%.

Asthma may be identified in association with pectus excavatum and carinatum. In a review of 694 consecutive

cases, 35 patients with asthma were identified (5.2%), a frequency comparable to that of asthma in the general pediatric population.⁸

Cause and Incidence

Ravitch reported that pectus excavatum may occur as frequently as 1 in 300 to 400 live births and that it is rare in blacks. It occurs more frequently in boys than girls, by an almost 4:1 ratio.⁹ Although the sternal depression appears to be caused by overgrowth of costal cartilages, the cause of pectus deformities is unknown. Lester attributed its development to an abnormality of the diaphragm, which tethered the sternum posteriorly.¹⁰ This theory was supported by the occurrence of pectus excavatum in children after repair of agenesis of the diaphragm and the frequent association of pectus excavatum and congenital diaphragmatic hernia.^{11,12} Histopathologic changes in the costal cartilages similar to those seen in scoliosis, aseptic osteonecrosis, and inflammatory processes are reported, but the cause of these changes and their significance are unknown.¹³

A family history of chest wall deformity in 37% of 704 patients suggests a genetic predisposition to pectus excavatum.¹⁴ Three of four siblings were affected in one family. Analysis of 34 families with more than one family member with pectus excavatum has shown a variable pattern of inheritance that appears to be multifactorial.¹⁵

A high incidence of chest wall deformities occurs in children with Marfan syndrome, and these deformities are often severe and usually accompanied by scoliosis.¹⁶ Pectus excavatum is also commonly seen in individuals with the abdominal musculature deficiency syndrome (prune-belly syndrome).¹⁷ Pectus excavatum also occurs in association with other myopathies and chromosomal

defects such as Turner syndrome. A summary of the associated musculoskeletal abnormalities is shown in Table 24-2.

Symptoms

Pectus excavatum is well tolerated in infancy and childhood. The anterior depression in an infant with a flexible chest may be accentuated by upper airway obstruction as from tonsillar and adenoidal hypertrophy, but this obstruction does not produce the pectus deformity. Older children may complain of pain in the area of the deformed cartilages or of precordial pain after sustained exercise. Symptomatic limitations to sustained exercise may also appear in these children and teenagers and limit their participation in athletic activities. Palpitations, presumably caused by transient atrial arrhythmias, are occasionally reported. These patients may have mitral valve prolapse.

Pathophysiology

The cardiopulmonary implications of the pectus excavatum deformity have been debated for many decades. Although some authors believe this deformity has a limited physiologic effect, many patients report increased stamina after surgical repair. These findings date back to the first surgical repair performed by Sauerbruch in 1913.¹⁸ The patient was an 18-year-old boy who developed dyspnea and palpitations with very limited exercise. Three years after his operation, he could work 12 to 14 hours a day without tiring and without palpitations. Anecdotal reports during the next 3 decades repeated this observation. Investigators have sought to identify the physiologic abnormality or combination of abnormalities that could explain this symptomatic improvement after surgery. Early physiologic measurements of cardiac and pulmonary function were crude and did not yield convincing evidence of a cardiopulmonary deficit. In many early studies the results fell within the broad range of normal values, if often at the lower limit.⁷ A recent analysis of a large multi-institutional cohort of 408 patients with pectus excavatum found that the median values for forced vital capacity (FVC) and forced expiratory volume

in 1 second (FEV₁) were 13% below predicted values and forced expiratory flow (FEF_{2.5%-75%}) median was 20% below the predicted value.¹⁹

A systolic ejection murmur is frequently present in individuals with pectus excavatum and it is magnified by a short interval of exercise. This murmur is attributed to the close proximity between the sternum and the pulmonary artery, which results in transmission of a flow murmur.

Electrocardiographic abnormalities are common and result from the abnormal configuration of the chest wall producing displacement of the heart into the left thoracic cavity.²⁰ Patients with a history of palpitations should have a 24-hour electrocardiogram to document the presence or absence of arrhythmias as well as an echocardiogram to evaluate for mitral valve prolapse. Resolution of these supraventricular arrhythmias has been anecdotally reported after correction of a pectus excavatum deformity.

Many authors attribute the symptomatic improvement in exercise tolerance after surgery to improvement in pulmonary function. This has been difficult to prove, however, with the wide range of pulmonary function that exists from individual to individual and its dependence on physical training and body habitus. Several of the key studies will be reviewed.

Pulmonary Function Studies

As early as 1951, Brown and Cook performed pulmonary evaluations on patients before and after surgical repair.²¹ They demonstrated that although vital capacity (VC) was normal, the maximum breathing capacity was diminished (50% or more) in 9 of 11 cases and increased an average of 31% after surgical repair. Weg and associates in 1967 evaluated 25 Air Force recruits with pectus excavatum and compared them with 50 unselected basic trainees.²² Although the lung compartments of both groups were equal, as were the VCs, the maximum voluntary ventilation was significantly lower in those with pectus excavatum than in the control population. Castile and coworkers in 1982 evaluated seven patients with pectus excavatum, five of whom were symptomatic with exercise.²³ The mean total lung capacity of the group was 79% of predicted. Flow volume configurations were normal, excluding airway obstruction as a cause of the symptoms. Workload tests demonstrated normal response to exercise in the dead space to tidal volume ratio and alveolar-arterial oxygen difference. The measured oxygen uptake, however, increasingly exceeded predicted values as workload approached maximum in the four “symptomatic” subjects with pectus excavatum. This pattern of oxygen consumption was different from that in normal subjects and in the three asymptomatic subjects with pectus excavatum in whom a linear response was seen. The mean oxygen uptake in the symptomatic subjects at maximal effort exceeded the predicted values by 25.4%. The three asymptomatic subjects, on the other hand, demonstrated normal linear oxygen uptake during exercise. Increased oxygen uptake suggests increased work of breathing in these symptomatic individuals despite the normal or mildly reduced VCs. Increases in tidal volume with

exercise were uniformly depressed in those with pectus excavatum.

Cahill and coworkers in 1984 performed pre- and postoperative studies in 5 children and adolescents with pectus carinatum and in 14 with pectus excavatum.²⁴ No abnormalities were demonstrated in the pectus carinatum group. The low normal VCs in excavatum patients were unchanged by operation, but a small improvement in the total lung capacity and a significant improvement in the maximal voluntary ventilation were seen. Exercise tolerance improved in those with pectus excavatum after operation, as determined by both total exercise time and maximal oxygen consumption. In addition, at any given workload, those with pectus excavatum demonstrated a lower heart rate, stable oxygen consumption, and higher minute ventilation after repair. Mead and associates in 1985 studied rib cage mobility by assessing intra-abdominal pressure.²⁵ Normal abdominal pressure tracings in pectus excavatum suggested normal rib cage mobility.

Blickman and colleagues in 1985 assessed pulmonary function in 17 children with pectus excavatum by xenon perfusion and ventilation scintigraphy before and after surgery.²⁶ Ventilation studies were abnormal in 12 children before surgery and improved in 7 after repair. Perfusion scans were abnormal in 10 children before surgery and improved after operation in 6 children. The ventilation-perfusion ratios were abnormal in 10 of the 17 children preoperatively and normalized after repair in 6 children.

Derveaux and associates in 1989 evaluated 88 patients with pectus excavatum and carinatum by pulmonary function tests before and 1 to 20 years after repair (mean was 8 years).²⁷ The surgical technique used a fairly extensive chest wall dissection. Preoperative studies were within the normal range (>80% of predicted) except in subjects who had both scoliosis and pectus excavatum. The postoperative values for FEV₁ and VC expressed as percentage of expected were decreased in all groups, although the absolute values at follow-up may have been greater than at preoperative evaluation. Improved chest wall configuration was confirmed by radiologic evaluation, so the relative deterioration in pulmonary function was not the result of recurrence of the pectus deformity. An inverse relationship was found between preoperative and postoperative function. Those with less than 75% of predicted function had improved function after surgery, but function was worse after repair if the preoperative values were greater than 75% of predicted. Almost identical results were found in a study by Morshuis and coworkers in 1994.²⁸ They evaluated 152 subjects before and a mean of eight years after surgery for pectus excavatum. These results of pulmonary evaluation were in contrast to the subjective symptomatic improvement reported by the patients and their improved chest wall configuration. The decline in pulmonary function in the postoperative studies was attributed to the operation because the preoperative pulmonary defect appeared to be stable regardless of the age at initial repair. Both studies were marred by the obvious lack of an age- and severity-matched control group without surgery.

Derveaux and colleagues in 1988 evaluated transpulmonary and transdiaphragmatic pressures at total lung capacity in 17 individuals with pectus excavatum.²⁹ Preoperative and long-term follow-up evaluations were performed a mean of 12 years apart. Reduced transpulmonary and transdiaphragmatic pressures demonstrated that the increased restrictive defect was produced by extrapulmonary rather than pulmonary factors, suggesting that surgery produced increased rigidity of the chest wall.

Wynn and others in 1990 assessed 12 children with pectus excavatum by pulmonary function tests and exercise testing.³⁰ Eight children had repair and were evaluated pre- and postoperatively. Four children had two sets of evaluations but no operation. A decline in total lung capacity was identified in the repaired children compared with stable values in the control group. Cardiac output and stroke volume increased appropriately with exercise before and after operation in both groups, and the operation was believed to have produced no physiologically significant effect on the response to exercise.

Kaguraoka and associates in 1992 evaluated pulmonary function in 138 individuals before and after repair of pectus excavatum.³¹ A decrease in VC occurred during the first 2 months after surgery, with recovery to preoperative levels by 1 year after operation. At 42 months, the values were maintained at baseline, despite a significant improvement in the chest wall configuration. Tanaka and coworkers in 1993 found similar results in individuals who had the more extensive sternal turnover technique; in fact, they demonstrated a more significant and long-term decrease in VC.³² Morshuis and coworkers in 1994 evaluated 35 subjects who had had pectus excavatum repaired as teenagers or young adults; their ages were 17.9 ± 5.6 years.³³ Preoperative evaluations were performed and repeated 1 year after surgery. Preoperative total lung capacity ($86.0 \pm 14.4\%$ of predicted) and VC ($79.7 \pm 16.2\%$) were significantly decreased from predicted values and decreased further after surgery ($-9.2 \pm 9.2\%$ and $-6.6 \pm 10.7\%$, respectively). The efficiency of breathing at maximal exercise improved significantly after operation. Exercise was limited by ventilation in 43% of the subjects before repair. A tendency toward improvement occurred after operation. However, the group with no ventilatory limitation initially demonstrated one after operation with a significant increase in oxygen consumption.

Quigley and colleagues in 1996 evaluated 36 adolescents with pectus excavatum and 10 age-matched healthy controls at baseline and then an average of 8 months after surgery in 15 subjects and 9 months in controls.³⁴ Adolescents with pectus excavatum had a decrease in VC compared with controls, although the mean values remained in the normal range. The mean total lung capacity was also normal. There was no difference in workload performance between subjects with pectus excavatum and the controls, with both groups achieving a similar duration and level of exercise. No significant change in pulmonary function tests was seen in follow-up in either group. The duration of exercise as well as the level of work increased significantly in those who had surgery but not in the controls. The absence of adverse effects on pulmonary function after surgery was

attributed to a less extensive surgical procedure than was used in the studies reported by Derveaux²⁹ and Morshuis^{28,33} and their colleagues. Several series report the effects on pulmonary function of the new minimally invasive repair of pectus excavatum (MIRPE) described by Nuss.^{35,36} In these series there were limited or no preoperative abnormalities and mild or no significant change after repair. Similar results were reported in a prospective study of 145 patients having MIRPE.³⁷ There was no improvement in static values 6 months after removal of the struts. The most recent study evaluated 77 patients who had pre- and postoperative testing.³⁸ This study demonstrated statistically significant improvements in the FEV₁, the FVC, and the oxygen pulse.

In a recent, multicenter study of patients with pectus excavatum, patients demonstrated a relatively small decrease in lung function preoperatively with improvement postsurgical correction of approximately 6% to 10%.³⁹ The improvement in lung function was slightly greater in those with the most severe degrees of depression of the sternum (CT index > 3.2). When pre- and postoperative exercise pulmonary function tests were compared, the exercise studies in postsurgical patients revealed a 10.2% increase in maximum oxygen uptake and a 19% increase in oxygen pulse. It is postulated that the latter is probably attributable to an increase in stroke volume. As in previous studies, although the mean decrease in pulmonary function preoperatively and the mean improvement postoperatively were statistically significant, the changes were only modest in magnitude after repair.

In composite, these studies of pulmonary function over the past 4 decades have failed to document consistent improvement in pulmonary function resulting from surgical repair. In fact, some studies have demonstrated deterioration in pulmonary function at long-term evaluation that was attributed to increased chest wall rigidity after repair. A meta-analysis of 12 of these studies revealed no statistically significant change in pulmonary function.⁴⁰ Despite this finding, workload studies have shown improvement in exercise tolerance after repair, suggesting there is a cardiac basis for this enhanced performance.^{24,41}

Cardiovascular Studies

Posterior displacement of the sternum can produce a deformity of the heart, particularly indentation of the right ventricle. Displacement of the heart to the left, often with a sternal "imprint" on the anterior wall of the right ventricle was demonstrated angiographically by Garusi and D'Ettorre in 1964,⁴² and Howard⁴³ demonstrated its resolution after surgical repair. Elevated right heart pressures have been reported by some authors, as have pressure curves similar to those seen in constrictive pericarditis. In 1962, Bevegård studied 16 individuals with pectus excavatum by right heart catheterization and exercise testing.⁴⁴ The physical work capacity in pectus excavatum at a given heart rate was significantly lower in the sitting than the supine position. Those with 20% or greater decline in physical work capacity from the supine to the sitting position had shorter

sternovertebral distances than did those with less decrease in their physical work capacity. The measured stroke volume at rest decreased from supine to sitting positions a mean of 40.3%, similar to normal subjects. In the supine position, stroke volume increased with exercise 13.2%. In the sitting position, the increase in stroke volume from rest to exercise was 18.5% for the pectus excavatum group, significantly lower ($P < 0.001$) than the 51% increase seen in normal subjects. Thus, in the pectus excavatum group, an increased cardiac output could be achieved primarily by increased heart rate because only limited enhancement of the stroke volume could occur. Intracardiac pressures measured at rest and with exercise were normal in all subjects despite this apparent limitation of ventricular volume.

Gattiker and Bühlmann in 1967 confirmed this limitation of the stroke volume in a study of 19 subjects.⁴⁵ In the upright position at a heart rate of 170 beats per minute, the physical work capacity was lower than in the supine position (mean 18% decrease) because of the decrease in stroke volume. Beiser and associates in 1972 performed cardiac catheterization in six adolescents and young adults with moderate degrees of pectus excavatum.⁴⁶ Normal pressure and cardiac index were obtained at rest in the supine position. The cardiac index during moderate exercise was normal, but the response to upright exercise was below that predicted in two patients and at the lower limit of normal in three patients. The cardiac index was 6.8 ± 0.8 L/min/m² compared with 8.9 ± 0.3 liter/min/m² in a group of 16 normal controls ($P < 0.01$). The difference in cardiac performance again appeared to be produced primarily by a smaller stroke volume in the group with pectus excavatum in an upright position. Stroke volume was 31% lower and cardiac output 28% lower during upright as compared with supine exercise. Postoperative studies were performed in three individuals, two of whom achieved a higher level of exercise tolerance after surgery. The cardiac index increased an average of 38%. Because heart rate at maximal exercise was not higher after repair, an enhanced stroke-volume response was responsible for this increase.

Peterson and associates in 1985 performed radionuclide angiography and exercise studies in 13 children with pectus excavatum.⁴⁷ Ten of 13 were able to reach the target heart rate before surgical repair, 4 without symptoms. After operation, all but 1 child reached the target heart rate during the exercise protocol, and 9 of 13 reached the target without becoming symptomatic. The left and right ventricular end-diastolic volumes were consistently increased after repair at rest, and the mean stroke volume was increased 19% after repair. These findings substantiated the ventricular volume changes previously demonstrated by cardiac catheterization, although an increase in the cardiac index was not demonstrated. Recent echocardiographic studies by Kowalewski and associates of 42 patients before and 6 months after surgery revealed statistically significant changes in the right ventricular volume indices after surgery.⁴⁸ There was no correlation seen, however, between the pectus index and the changes in the right ventricular volume indices.

Malek and coauthors (2003) performed maximal exercise testing and pulmonary function tests on 21 individuals with pectus excavatum, 18 of whom routinely did aerobic exercise.⁴¹ Their maximum oxygen uptake and oxygen pulse were significantly lower than expected. These limitations were attributed to cardiovascular and not ventilatory factors and resulted in an abnormally low threshold for lactate accumulation. Of note, subjects with a Haller index greater than 4.0 were eight times more likely to have reduced aerobic capacity than those with a lower severity index.

Results of cardiac function have more recently been assessed in patients having the MIRPE procedure.³⁶ In 11 patients, an increase was demonstrated in the stroke volume measured echocardiographically 3 months after repair to which subjective improvement in exercise tolerance was attributed.

A meta-analysis was performed of eight studies (representing 169 patients), which reported quantitative data on the cardiovascular function of patients before and following repair.⁴⁹ The analysis suggested that surgical repair did not significantly improve cardiovascular function.

A recent study of 75 teenagers (49 with pectus excavatum and 26 controls) demonstrated a lower cardiac index in those with pectus excavatum during submaximal exercise, whereas there was no difference in heart rate or increase in heart rate between the two groups.⁵⁰ A follow-up study a year following surgery with a modified Nuss procedure demonstrated a significant increase in the patients following surgery, although the cardiac index was still significantly lower compared with the controls. Repeat studies 3 years after surgery and following strut removal revealed no difference in cardiac index or FEV₁ between the patients and controls.⁵¹ Additional studies are needed to further define the relationship between pectus excavatum and cardiopulmonary function. Recent dynamic or exercise studies have been most promising in this area. Methods to more effectively evaluate preoperative cardiopulmonary function are needed to identify which children may achieve symptomatic and physiologic improvement from surgical repair.

Echocardiographic Studies of Mitral Valve Prolapse

Bon Tempo, Salomon, and Schutte and their associates reported mitral valve prolapse in patients with narrow anterior-posterior chest diameters, anterior chest wall deformities, and scoliosis.⁵²⁻⁵⁴ Prospective echocardiographic studies of adults with pectus excavatum demonstrated mitral valve prolapse in six of 33 (18%) subjects studied by Udoshi and associates and in 11 of 17 subjects (65%) of Saint-Mezard and colleagues.^{55,56} Anterior compression of the heart by the depressed sternum may deform the mitral annulus or the ventricular chamber and produce mitral valve prolapse in these patients. Preoperative evaluation by echocardiogram of children and adolescents with pectus excavatum by Shamberger and associates identified 23 with mitral valve prolapse.⁵⁷ Postoperative studies did not demonstrate mitral valve prolapse in 10 (43%) of these children, suggesting its resolution after correction of the chest wall deformity.

Coln and coauthors performed echocardiography on subjects during exercise (123 preoperative and 107 postoperative).⁵⁸ They demonstrated chamber compression in 117 (95%) before surgery and in none of the patients after repair. They also found in subjects with chamber compression resolution of mitral valve prolapse (16 of 23) and mitral valve regurgitation (28 of 29) following repair as had been previously demonstrated by the author. Symptoms related to exertion reported in 106 (86%) of the subjects resolved remarkably in all, which was attributed to the cardiac effects of repair.

Surgical Repair

The first surgical corrections of pectus excavatum were reported by Meyer in 1911 and Sauerbruch in 1920, and Ochsner and DeBakey summarized the early experience with various techniques.^{18,59,60} In 1949, Ravitch reported a technique that included excision of all deformed costal cartilages with the perichondrium, division of the xiphoid from the sternum, division of the intercostal bundles from the sternum, and a transverse sternal osteotomy securing the sternum anteriorly in an overcorrected position.⁶¹ Kirschner wire fixation was used in the first two patients and silk suture fixation in later patients.

Baronofsky (1957) and Welch (1958) subsequently reported a technique for the correction of pectus excavatum that emphasized total preservation of the perichondrial sheaths as well as the attachment of the upper sheaths and intercostal bundles to the sternum.^{62,63} Anterior fixation of the sternum was achieved with silk sutures. Haller and associates later developed a technique which they labeled as *tripod fixation*.⁶⁴ Subperichondrial resection of the abnormal cartilages is performed followed by a posterior sternal osteotomy. The most cephalad normal cartilages are then divided obliquely in a posterolateral direction. When the sternum is elevated, the sternal ends of the cartilage rest on the costal ends, providing further anterior support of the sternum. Support of the sternum by metallic struts after mobilization of the costal cartilages has been promoted by several authors. Rehbein and Wernicke developed struts that could be placed into the marrow cavity of the ribs at the costochondral junction.⁶⁵ An arch was then formed by the struts anterior to the sternum, and the sternum was secured to this arch. Paltia and associates placed a transverse strut through the caudal end of the sternum, firmly fixing its location.⁶⁶ The two ends of the strut are supported by the ribs laterally. Adkins and Blades, and Jensen and associates, used retrosternal elevation by a metallic strut.^{67,67a} Willital used a similar retrosternal strut after creating multiple chondrotomies in the costal cartilages to provide flexibility.⁶⁸ Recent innovations in these methods include bioabsorbable struts, or use of Marlex mesh or a Dacron vascular graft as a strut, but there is no evidence these methods are preferable to traditional methods with metallic struts.⁶⁹ Robicsek and Fokin described a large series of chest wall deformities.⁷⁰ For those patients with pectus excavatum, the sternum is mobilized more extensively with this technique than in others, except for the sternal turnover. The sternum is divided from the intercostal muscles and perichondrial sheaths from its tip to

the upper extent of the deformity. It is then supported in an anterior position by a “hammock” of Marlex mesh, which is sewn to the ends of the ribs to each side. The advantages of this extensive mobilization and permanent implantation of the mesh are not clear. No randomized studies have compared the recurrence or complication rates between suture or strut fixation techniques. Oelsnitz and Hecker and coworkers, using suture fixation, reported satisfactory repairs in their large series in 90% to 95%.^{2,13}

The *sternal turnover* was first proposed by Judet and Judet in 1954 and Jung in 1956 in the French literature.^{71,72} The sternum is mobilized and the costal cartilages are divided, allowing the sternum to be rotated 180 degrees. Wada and colleagues in 1970⁷³ reported a very large series from Japan using this technique, which is essentially a free graft of sternum. It is a radical approach and has been associated with major complications if infection occurs. Modifications of this technique by Taguchi and associates in 1975 have involved either preservation of the internal mammary vessels by wide dissection or reimplantation of the internal mammary artery.⁷⁴ These modifications were developed because of the reported incidence of osteonecrosis and fistula formation, which occurred in up to 46% of patients older than 15 years.

Allen and Douglas implanted Silastic molds into the subcutaneous space to fill the depression in pectus excavatum.⁷⁵ Although this approach may improve the external contour of the chest, extrusion of the molds has occurred, and this method does nothing to increase the volume of the thoracic cavity or relieve compression on the heart. Other authors have reported favorable cosmetic results in adults with no pulmonary restrictions but with a significant frequency of seroma and hematoma formation.^{76,77} Schier and colleagues described use of a suction device placed over the chest in children and adults with pectus excavatum and early results were encouraging, although the durability of the correction was not established.⁷⁷ Haecker and Mayr⁷⁸ described a similar device. Although improvement was seen, only 14.7% of the patients had the sternum lifted to a “normal” position after 12 months of therapy.

A randomized postoperative study comparing the use of an epidural catheter versus patient-controlled analgesia for pain control demonstrated that pain scores favored the epidural approach early in the postoperative period and patient-controlled analgesia in the later period.⁷⁹ The epidural analgesia technique required longer time in the operating room, an increased number of calls to the pain service, and greater hospital charges.

Minimally Invasive Repair of Pectus Excavatum

A method of elevation of the sternum with a retrosternal bar without resection or division of the costal cartilages was first reported by Nuss in 1998.⁸⁰ He repaired 42 patients under 15 years of age (median age 5 years) by placing a convex steel bar under the sternum and anterior to the heart through small bilateral thoracic incisions. A long clamp was passed blindly behind the sternum and

out an opening in the contralateral chest (Fig. 24-3). A tape was then drawn across the chest in the clamp and used to pull the bar through the pleural cavity and anterior to the pericardium. The bar was initially placed with the concave side anteriorly and then it was rotated once it was in position (see Fig. 24-3). The bar was left in position for 2 years before removal when presumed permanent remodeling of the cartilages had occurred. Although Nuss in his initial report warned that the “upper limits of age for this procedure require further evaluation,” the technique has been widely used in older patients and Hebra and colleagues have reported the use of this technique in adults.⁸¹ In 2002 the results by Nuss and his associates using this technique in 303 patients were reported by Croitoru.⁸² This included an older group of children than in the initial report (range 21 months to 29 years; median age 12.4 years). Two bars were required in 12.5% of the patients. Routine use of thoracoscopy to avoid cardiac injury was instituted in 1998. Lateral stabilizers were placed in 69.4% of the cases and were routinely used after 1998 and were wired to the bar in 65.4% of cases. Recommended duration for leaving the bars in the chest is now 3 years. Epidural analgesic was used for 2 to 4 days and the median length of stay was 5 days with a range of 3 to 10 days. The frequency of early complications was low. They included pneumothorax requiring aspiration 1.0%, pericarditis 2.3%, with only 0.3% requiring drainage, pneumonia 0.7%, hemothorax 0.3%, transient extremity paralysis 0.3%, superficial wound infection 2.3%, and bar infection requiring eventual removal of the bar 0.7%.

Late complications in this series included bar displacement requiring repositioning in 8.6% of cases, which included a high proportion (over 50%) of patients in whom a stabilizer was not used or in patients where the stabilizer was not wired to the bar. When both modifications were used, displacement occurred in only 5% of the patients. An unexpected occurrence of allergies to the metal bar was encountered in 1% of the patients who presented with rashes in the area of the bars. This required conversion to bars composed of other alloys. Late hemothorax occurred in two patients, one secondary to undefined trauma. The occurrence of a mild overcorrection in the deformity was seen in 3.6% and a pectus carinatum deformity developed in 1.3%, all of whom had either Marfan syndrome or Ehlers-Danlos syndrome. The reported outcome of children in this large series was excellent appearance in 84.5%, good in 14.8%, and failed in only 1 patient; however, the bars had been removed at the time of the report in only 23.4% of the patients.

A more recent summary by Shin and associates of the infectious complications in a consecutive series of 863 patients showed a 1.5% incidence.⁸³ This included six bar infections, four cases of cellulitis, and three stitch abscesses. Antibiotics and surgical drainage resolved the infection in three of the bar infections, and removal of the bar was required in three patients (in one patient 3 months after surgery and in the other two patients 18 months after surgery). Organisms involved were predominantly *Staphylococcus aureus* in 83% of the cases. This success of preserving the struts despite infectious

complications was mirrored by the experience in two subsequent reports.^{84,85}

Allergy to the retrosternal bars was also identified in 2.2% of the patients having MIRPE by Nuss and his group.⁸⁶ Most patients (63%) presented with rash and erythema, 32% had pleural effusions, and 15% were diagnosed on preoperative screening. It is obviously critical to distinguish between allergic and infectious complications. The importance of placing the bars and stabilizers in a subcutaneous and not a submuscular position to

avoid extra osseous bone formation around the strut and increased blood loss at the time of removal has been demonstrated.⁸⁷

Hebra and associates reported the results of a survey of members of the American Pediatric Surgery Association who had used the minimally invasive (Nuss) technique.⁸⁸ Thirty institutions contributed 251 cases, although it should be noted that 42% were performed by one surgeon. The complications reported were similar to those of Nuss and his associates, but the frequency was

FIGURE 24-3 ■ **A**, The length of the pectus bar is determined by measuring the distance from the right midaxillary line to the left midaxillary line and subtracting 2 cm or 1 inch, because the bar takes a shorter course than the tape measure. The measurement is done over the area of the deepest depression that is still part of the sternum. The bar is bent to the desired convex configuration, making note that the center of the bar should be flat for 2 to 4 cm to allow greater stability. **B**, A thoracoscope is inserted into the right chest two intercostal spaces below the planned bar placement to check that the internal anatomy corresponds with the external markings and to look for unexpected pathology. If all is well, then the lateral thoracic incisions are made in the region of the midaxillary line and subcutaneous tunnels are created to the greatest apex of the pectus deformity (X). The X's represent the entrance and exit sites of the bar from inside the chest. They are in the intercostal space that is in the same horizontal place as the deepest depression, and care should be taken that they are placed medial to the greatest apex of the chest. **C**, Skin tunnels are created above the muscle starting from each of the lateral thoracic incisions to the top of the pectus ridge on each side. The tunnels should be created so that the entry and exit sites of the bar from inside the chest are medial to the top of the pectus ridge on each side. With the thoracoscope in place, a tonsil clamp is inserted into the subcutaneous tunnel on the right and a blunt thoracostomy is created at the site marked X, taking care not to injure the intercostal vessels, lung, or pericardium. **D**, Under continued thoracoscopic visualization, a pectus introducer (Biomet Microfixation, Jacksonville, FL) is inserted into the chest through the right tunnel and thoracostomy site at the top of the pectus ridge. With great care and thoracoscopic guidance, the pleura and pericardium are dissected off the undersurface of the sternum, creating a substernal tunnel. The introducer is slowly advanced across the mediastinum and brought out through the corresponding intercostal space on the left and advanced out of the incision on the contralateral side. Again, this exit site is medial to the top of the pectus ridge. **E**, A 30-degree thoracoscope facilitates visualization during the substernal dissection, and care is taken to keep the point of the dissector underneath the sternum at all times to push the heart out of the way of the dissection plane. During the dissection the ECG monitor should be turned to maximum volume to listen for any ectopy or arrhythmias. **F**, The introducer is pushed out of the thorax through the previously marked intercostal space (x) on the left and advanced out through the corresponding tunnel and incision. When the introducer is fully in place, the sternum is elevated by lifting the introducer on each side, thus correcting the pectus excavatum. The sternum is lifted out of its depressed position with the introducer numerous times. This is facilitated by pressing down on the lower chest wall while lifting the introducer. **G**, Once the sternal depression has been corrected, umbilical tape is attached to the introducer and the introducer is slowly withdrawn from the chest cavity with the umbilical tape attached.

FIGURE 24-3, cont'd ■ H, The pectus bar that was previously bent into a convex shape is then attached to the umbilical tape and slowly guided through the right subcutaneous tunnel under thoracoscopic visualization and guided through the substernal tunnel with its convexity facing posteriorly until it emerges on the contralateral side. **I,** The pectus bar is positioned inside the chest with its convexity facing posteriorly and an equal amount of bar protruding on each side. Using the specially designed bar flippers (Biomet Microfixation, Jacksonville, FL), the bar is rotated 180 degrees giving instant correction to the pectus deformity. The sides of the bar should be resting comfortably against the musculature and should not be too tight or too loose. If the bar does not fit snugly on each side because of pressure on the middle, the bar can be reflipped and molded as necessary while still in place in the chest. **J,** The bar is stabilized by attaching a stabilizer to the left end of the bar and wiring the bar and stabilizer together with No. 3 surgical steel wire. The stabilizer and bar are also secured by placing numerous interrupted absorbable sutures through the holes in the bar and adjacent fascia. An additional stabilizing technique uses a laparoscopic "auto-suture" needle to place multiple 0 PDS or Vicryl sutures around the bar and underlying ribs with thoracoscopic guidance. (From Shamberger RC, Nuss D, Goretsky MJ: Surgical treatment of chest wall deformities. In Spitz L, Coran AG, editors: *Operative pediatric surgery*, ed 6, London, 2006, Hodder Arnold. With permission.)

higher, presumably because the procedures were performed by more individuals less familiar with the operation. Displacement of the bar occurred in 9.2% of cases and pneumothorax requiring tube thoracostomy in 4.8%. Less frequently encountered complications included thoracic outlet syndrome, pericarditis, blood loss requiring a transfusion, cardiac injury, persistent cardiac arrhythmias, and erosion of the sternum by the bar. Many of the surgeons had adopted the use of thoracoscopy to improve the safety of passing the clamp anterior to the heart. Other surgeons elevate the sternum with a bone hook during passage of the clamp to open the retrosternal space anterior to the heart.

Engum and coauthors reported their series of 21 patients with a mean age of 8.2 years.⁸⁹ Their patients had an average hospital stay of 4.9 days, which was comparable with that of the open repair. Complications encountered in their series were similar to the experience of others and included rotation of the bar, production of a marked pectus carinatum deformity, progressive chest wall asymmetry, and chronic persistent pain requiring removal of the bar in one case.

Molik and colleagues later enlarged this single institution review and in a retrospective analysis compared 68

patients with standard surgical repair with 35 patients with a Nuss repair.⁹⁰ The Nuss procedure required less time (3.3 hours) compared with the open technique (4.7 hours), but had a higher complication rate (43%) than the open method (20%). Four patients with the standard operation (6%) and eight with the Nuss technique (29%) required reoperation. Length of stay was comparable between the open (4.8 days) and Nuss (4.0 days) techniques. The Nuss patients had a higher frequency of epidural analgesics postoperatively and an increased duration of patient-controlled analgesia after surgery.

Fonkalsrud and associates reported a similar retrospective comparison of the two techniques, each used at one institution.⁹¹ During a 5-year interval, 68 patients had the minimally invasive procedure and 139 had the open technique. There was a higher incidence of reoperations and hospitalizations in the Nuss group, but it was noted that 90% of the complications of this method occurred in the first 25 cases, again clearly demonstrating the role of experience in determining the frequency of surgical complications. It was difficult to determine in this study whether the differences noted in the use of epidural catheters and intravenous narcotics was attributable to truly different patient requirements or was a

manifestation of institutional bias for analgesic techniques. There was a shorter mean hospitalization noted for the open procedure (2.9 days) compared with the minimal access procedure (6.5 days), and a similar difference between mean time before return to work or school (12 vs. 18 days). These authors concluded that “long-term follow-up also will be required to assure both health professionals and the public that this is the procedure of choice for patients with pectus excavatum.”

The occurrence of “overcorrection” of the deformity or production of a true carinate deformity was first reported by Croitoru and associates and was associated with underlying connective tissue disorders (Marfan syndrome and Ehlers-Danlos syndromes).⁸² It was reported, however, by Hebra to have occurred in an otherwise healthy 13-year-old boy 1 year after Nuss repair and by others following both MIRPE and open repair.^{92,93} What factors predispose some patients to this complication is not understood.

Other rare complications for the MIRPE include those of exsanguinating hemorrhage during removal of the strut resulting from laceration of a pulmonary vessel and bilateral sternoclavicular dislocation; cardiac tamponade and shock produced by erosion of the aorta by a strut that had rotated 90 degrees; and a near-fatal hemorrhage from erosion of the internal mammary vessel by a bar that had rotated 45 degrees.⁹⁴⁻⁹⁶ Thoracic outlet syndrome presenting with brachial plexus compression has also been reported following repair of a severe asymmetrical depression,⁹⁷ as has mechanical occlusion of the inferior vena cava at the level of the diaphragm, both of which were relieved by removal of the strut.⁹⁸

Kelly and colleagues have recently summarized their large experience with 1,215 patients with the MIRPE and reviewed the changes they have made to the procedure.⁹⁹ One bar was placed in 69% and two bars were required in 30% of their patients; 95.8% of the patients had a good or excellent surgical outcome at the time of bar removal. Complications with bar displacement decreased from 12% in the first decade to 1% in the second. Allergy to nickel was identified in 2.8% of patients, the vast majority prior to surgery. Wound infection occurred in 1.4% (17 patients) of whom 4 required surgical drainage. During the interval of this study, the median age at surgery has gone from 6 years to 14 years. Modifications of the technique that occurred during the duration of the study include routine use of unilateral or bilateral thoracoscopy; techniques to minimize risk of dissection between the sternum and heart in patients with severe depressions, including elevation of the sternum manually through an infraxiphoid incision or first placing a more superior transmediastinal tunnel and leaving the introducer in place, elevating the sternum while dissecting the lower tunnel; use of titanium bars when a metal allergy is identified; using a bar length that is 1 inch shorter than the measurement from right to left midaxillary line; more frequent use of two bars in patients with severe depressions or older patients; and use of a metal stabilizer to decrease the risk of rotation of the bar.

The MIRPE has also been used for patients with recurrent pectus depressions. A report of 100 patients demonstrated that this approach was generally safe and

effective but that patients with a prior MIRPE may have extensive pleural adhesions requiring decortication and patients with a prior open procedure may have acquired thoracic dystrophy and require multiple bars and are at a greater risk of complications.¹⁰⁰

A prospective multi-institutional study of patients undergoing repair of pectus excavatum has been completed. Early reports from this study suggest that the pain and complications from the MIRPE and open procedures are similar and that repair can be accomplished with limited risks to the patients.¹⁰¹ A subsequent report from this study demonstrated by use of a validated survey tool that preoperative psychosocial functioning was unrelated to the objective severity of the pectus depression by CT index.¹⁰² Both patients and their parents reported significant positive postoperative changes in both physical and psychosocial functioning, including less social self-consciousness and a more favorable body image.

Children should be followed long-term after repair by any technique until they reach full stature. Only by so doing can each surgeon assess the ultimate results of his or her surgical technique. Regrettably, recurrence can occur until full stature is achieved.

Open Surgical Repair of Pectus Excavatum

The open surgical technique for correction of pectus excavatum is depicted in [Figure 24-4](#). In girls, particular attention is taken to place the incision within the projected inframammary crease, thus avoiding the complications of breast deformity and development described by Hougaard and Arendrup.¹⁰³ Skin flaps are mobilized by electrocautery to the angle of Louis superiorly and a shorter distance to the xiphoid inferiorly. Pectoral muscle flaps are elevated off the sternum and costal cartilages, preserving the entire pectoralis major and portions of the pectoralis minor and serratus anterior muscles in the flap (see [Fig. 24-4A](#)). Ellis and associates have described elevating the skin and muscle together in a single flap, which is a reasonable but not widely adopted alternative method.¹⁰⁴

Perioperative antibiotics are used, giving one dose of cefazolin immediately before operation and three postoperative doses. The Hemovac drain (Snyder Laboratories, New Philadelphia, OH) is removed when the drainage is less than 15 mL for an 8-hour period. All patients are warned to avoid aspirin and nonsteroidal anti-inflammatory agent-containing compounds for 2 weeks before surgery.

The authors currently use the retrosternal bar (Baxter Healthcare, Deerfield, IL) for internal fixation to secure the sternum firmly in an anterior position and to avoid the need to skeletonize the sternum to achieve adequate mobility for suture fixation. Although correction of pectus excavatum is technically most easily performed in a young child, there is increasing concern about long-term recurrence in these children as well as impairment in the growth of the chest wall. Current practice is to delay surgery until the children are well into their pubertal growth. At this age, the chest has less remaining growth and opportunity for recurrence of the pectus

FIGURE 24-4 ■ Open surgical technique for repair of pectus excavatum. **A**, A transverse incision is placed below and well within the nipple lines and, in females, at the site of the future inframammary crease. The pectoralis major muscle is elevated from the sternum along with portions of the pectoralis minor and serratus anterior bundles. **B**, The correct plane of dissection of the pectoral muscle flap is defined by passing an empty knife handle directly anterior to a costal cartilage after the medial aspect of the muscle is elevated with electrocautery. The knife handle is then replaced with a right-angle retractor, which is pulled anteriorly. The process is then repeated anterior to an adjoining costal cartilage. Anterior distraction of the muscles during the dissection facilitates identification of the avascular areolar plane and avoids entry into the intercostal muscle bundles. Muscle elevation is extended bilaterally to the costochondral junctions of the third to fifth ribs and a comparable distance for ribs 6 and 7. **C**, Subperichondrial resection of the costal cartilages is achieved by incising the perichondrium anteriorly. It is then dissected away from the costal cartilages in the bloodless plane between perichondrium and costal cartilage. Cutting back the perichondrium 90 degrees in each direction at its junction with the sternum (*inset*) facilitates visualization of the back wall of the costal cartilage. **D**, The cartilages are divided at their junction with the sternum with a knife having a Welch perichondrial elevator held posteriorly to elevate the cartilage and protect the mediastinum (*inset*). The divided cartilage can then be held with an Allis clamp and elevated. The costochondral junction is preserved with a segment of costal cartilage on the osseous ribs by incising the cartilage with a scalpel. Costal cartilages three through seven are generally resected, but occasionally the second costal cartilages must be removed if posterior displacement or funneling of the sternum extends to this level, as may be seen in older patients (see Fig. 24-1). Segments of the sixth and seventh costal cartilages are resected to the point where they flatten to join the costal arch. Familiarity with the cross-sectional shape of the medial ends of the costal cartilages facilitates their dissection. The second and third cartilages are broad and flat, the fourth and fifth are circular, and the sixth and seventh are narrow and deep.

Continued

FIGURE 24-4, cont'd ■ **E**, The sternal osteotomy is created above the level of the last deformed cartilage and the posterior angulation of the sternum, generally the third cartilage but occasionally the second. Two transverse sternal osteotomies are created through the anterior cortex with a Hall air drill (Zimmer USA, Warsaw, IN) 3 to 5 mm apart. **F**, The base of the sternum and the rectus muscle flap are elevated with two towel clips, and the posterior plate of the sternum is fractured. The xiphoid can be divided from the sternum with electrocautery, allowing entry into the retrosternal space. This step is not necessary with the use of a retrosternal strut unless the xiphoid is protruding anteriorly when the sternum is in its corrected position. Preservation of the attachment of the perichondrial sheaths and xiphoid avoids an unsightly depression that can occur below the sternum. **G**, Correction of the abnormal position of the sternum is achieved by creation of a wedge-shaped osteotomy, which is then closed with elevation by the strut, bringing the sternum anteriorly into a slightly overcorrected position. **H**, This figure demonstrates the use of both retrosternal struts and Rehbein struts. Rehbein struts are inserted into the marrow cavity (*inset*) of the third or fourth rib, and the struts are then joined medially to create an arch anterior to the sternum. The sternum is sewn to the arch to secure it in its new anterior position. The retrosternal strut is placed behind the sternum and is secured to the rib ends laterally to prevent migration. **I**, Anterior depiction of the retrosternal strut. The perichondrial sheath to either the third or the fourth rib is divided from its junction with the sternum, and the retrosternal space is bluntly dissected to allow passage of the strut behind the sternum. It is secured with two pericostal sutures laterally to prevent migration. The wound is then flooded with warm saline and cefazolin solution to remove clots and inspect for a pleural entry. A single-limb medial Hemovac drain (Snyder Laboratories, New Philadelphia, OH) is brought through the inferior skin flap to the left of the sternum and placed in a parasternal position to the level of the highest resected costal cartilage. **J**, The pectoral muscle flaps are secured to the midline of the sternum, advancing the flaps inferiorly to obtain coverage of the entire sternum. The rectus muscle is then joined to the pectoral muscle flaps, closing the mediastinum. excavatum (Fig. 24-5). Fonkalsrud also recommends delay until at least 10 years of age because of recurrence most frequently occurring during pubertal growth.⁹¹ In contrast, Humphreys and Jaretzki and Backer and associates have found no correlation between the age at repair and frequency of recurrence.^{105,106}

Complications are few and relatively unimportant, except for major recurrence, which occurred in 17 of 704 patients in one series (Table 24-3).¹⁴ Pneumothorax occurred in 2% of the patients and required only observation or aspiration. Tube thoracostomy was required in only four patients in the entire series and in no patients

during the last 2 decades of the report. Wound infection is rare with use of perioperative antibiotic coverage.

The most distressing complication after surgical correction of pectus excavatum is major recurrence of the deformity. It is difficult to predict which patients will have a major recurrence, but it appears to occur with increased frequency in children with poor muscular development and an asthenic or “marfanoid” habitus. All children with Marfan syndrome should be repaired with strut fixation because of the high risk of recurrence reported without strut fixation. Scherer and associates reported a low recurrence rate (1 of 8 cases) using a retrosternal strut.¹⁶ Redlinger and colleagues reported their results with the MIRPE procedure in patients with

Marfan syndrome (33 patients) and marfanoid features (212 patients).¹⁰⁷ The patients with Marfan syndrome had more severe deformities and required multiple bars for correction. The recurrence rate of these two groups was not significantly different from patients without Marfan syndrome or marfanoid features, and clinical results were similar between all groups.

Although recurrences appear symmetrical, many are in fact right sided, with a deep right parasternal gutter and sternal obliquity. The third, fourth, and fifth rib ends migrate medially, with apparent “foreshortening” of the costal cartilages. Correction of recurrent pectus excavatum is generally a formidable task. Sanger and associates reported their experience in secondary correction.¹⁰⁸ They resected the regenerated fibrocartilage plate, repeated the sternal osteotomy, and closed the pectoral muscles behind the sternum. Ten patients had an early good result. In the Boston Children’s Hospital experience, 12 children and adolescents underwent secondary repair. Resection of the segments of the third to fifth costal cartilages was necessary to correct the deformity. After clearing the tip of the sternum, resection of the left fibrocartilage plate to the level of the third or second perichondrial sheath allowed the sternum to be brought forward and rotated into an acceptable position. Ten of 12 repeat operations were accomplished without pleural entry. Follow-up of patients with secondary correction ranged from 10 to 17 years. Eight had acceptable thoracic contour, two had a broad shallow depression, and two had frank recurrence. I recommend use of strut fixation on all patients with secondary repair because cartilage regeneration will be slower and less adequate than that after primary operation. Successful repair of recurrent pectus

excavatum has also been reported using the MIRPE technique.^{109,110}

In 1990, Martinez and associates first described a deficiency in thoracic growth in children after repair of pectus excavatum during the preschool years.¹¹¹ Subsequently in 1996, Haller reported three boys who presented in their teens with apparent limited growth of the ribs after resection of the costal cartilages at an early age.¹¹² This produced a bandlike narrowing of the mid chest, which was labeled acquired Jeune disease by the authors (Fig. 24-6). In some cases, the first and second ribs in which the costal cartilages had not been resected had relative overgrowth, producing anterior protrusion of the upper sternum (see Fig. 24-6C). Haller attributed this to injury of the costochondral junctions during surgical repair.¹¹² As these junctions are the longitudinal growth centers for the ribs, early operation resulted in decreased growth of the ribs and of the sternum resulting from injury to its growth centers or vascular supply. Martinez and associates demonstrated experimentally in 6-week-old rabbits that resection of the costal cartilages produced a marked impairment in chest growth, particularly the anterior-posterior diameter, during a 5.5-month period of observation.¹¹¹ Less severe impairment occurred if only the medial three fourths of the costal cartilage was resected, preserving the growth centers at the costochondral junction. This impairment was attributed to fibrosis and scarring within the perichondrial sheaths. Perichondrial sheaths, bone, or other prosthetic tissues that cannot grow also should not be joined posterior to the sternum because they will form a bandlike stricture across the chest. This complication of delayed thoracic growth was described primarily in children repaired in early childhood and can be avoided by delaying surgery until the children are older. Preservation of the costochondral junction by leaving a segment of the cartilage on the osseous portion of the rib may partially minimize growth impairment. Weber and Kurkchubasche described a method of improving the severe pulmonary impairment

encountered in one patient with the “acquired Jeune syndrome.”¹¹³ A sternotomy was performed and wedged open permanently with rib struts. The pleura was opened bilaterally along with subperichondrial resection of six ribs. Pulmonary function was improved after the procedure in this patient. A subsequent report involving 10 patients further substantiates the efficacy of this technique to improve pulmonary function in 8 of the 10 cases.¹¹⁴ Patients are followed after surgery to full growth: age 16 for girls and age 19 for boys. Use of clinical and Moiré photography for initial evaluation and follow-up studies leads to improved clinical assessment of results and obviates the need for multiple radiographic examinations.¹¹⁵

PECTUS CARINATUM

Pectus carinatum, an anterior protrusion of the sternum or chest wall, is much less frequent than pectus excavatum: 16.7% of all chest wall deformities in the Boston Children’s Hospital experience. The anterior protrusion occurs in a spectrum of configurations often divided into four categories (Table 24-4).¹¹⁶ The most frequent form, termed *chondrogladiolar* by Brodtkin, consists of anterior protrusion of the body of the sternum with protrusion of the lower costal cartilages.¹¹⁷ It is described as appearing as if a giant hand had pinched the chest from the front, forcing the sternum and medial portion of the costal cartilages forward and the lateral costal cartilages and ribs inward (Fig. 24-7).¹¹⁸ Asymmetrical deformities with anterior displacement of the costal cartilages on one side and normal cartilages on the contralateral side are less common (Fig. 24-8). Mixed lesions have a carinate deformity on one side and a depression or excavatum deformity on the contralateral side, often with sternal rotation. Some authors classify these as a variant of the excavatum deformities. The least frequent deformity is the *chondromanubrial* or “pouter pigeon” deformity with protrusion

FIGURE 24-6 ■ Sequence of photographs demonstrating deterioration in the quality of a repair that can occur with time. This boy had an initial excellent result from a Welch repair with suture fixation of the sternum at age 4 years 3 months. The follow-up photographs at 7 years 6 months (A), 9 years 3 months (B), and 12 years 9 months (C) demonstrate progressive depression of the sternum and costal cartilages and relative “overgrowth” of the upper chest.

of the upper chest involving the manubrium and second and third costal cartilages with relative depression of the body of the sternum (Fig. 24-9).

Cause

The cause of pectus carinatum is no better understood than that of pectus excavatum. It appears as an overgrowth of the costal cartilages with forward buckling of the cartilages and anterior displacement of the sternum. Again, there is a clear-cut increased family incidence, which suggests a genetic basis. In a review by the author and colleagues of 152 patients, 26% had a family history of chest wall deformity and 12% of scoliosis.¹¹⁶ It is much more frequent in boys than in girls by a 3 : 1 ratio. Scoliosis and other deformities of the spine are the most common associated musculoskeletal anomalies (Table 24-5).¹¹⁶

Pectus carinatum is rarely present at birth, and in almost one half of the patients, the deformity was not

identified until after the 11th birthday (Fig. 24-10). The deformity often progresses during early childhood, particularly in the period of rapid growth at puberty. The chondromanubrial deformity, in contrast with the chondrogladiolar form, is often noted at birth and is associated with a truncated, comma-shaped sternum with absent sternal segmentation or premature obliteration of the sternal sutures (Fig. 24-11). Currarino and Silverman described its association with an increased risk of congenital heart disease.¹¹⁹ Lees and Caldicott reviewed 1915 thoracic radiographs and identified 135 children with sternal fusion anomalies.¹²⁰ Eighteen percent of these children had documented congenital heart disease.

Surgical Repair

Correction of carinate deformities has had a colorful history, beginning with the first repair by Ravitch in 1952

FIGURE 24-9 ■ **A**, A 15-year-old boy with the chondromanubrial deformity. Note the posterior depression of the lower sternum, accentuated by the anterior bowing of the second and third costal cartilages. **B**, After repair, the sternal contour is improved and costal cartilages are reformed in a more appropriate fashion.

FIGURE 24-10 ■ Age at appearance of pectus carinatum deformity in 141 infants and children. Note the appearance of protrusion in almost one-half of the children at puberty. (From Shamberger RC, Welch KJ: Surgical correction of pectus carinatum. *J Pediatr Surg* 22:48–53, 1987. With permission.)

of an upper chondromanubrial deformity.¹²¹ He resected multiple costal cartilages and performed a double sternal osteotomy. In 1953, Lester reported two methods of repair for a lower chondrogladiolar deformity.¹²² The first approach, resection of the anterior portion of the sternum, was abandoned because of excessive blood loss and unsatisfactory results. The second method, subperiosteal resection of the entire sternum, was a no less radical technique. Chin (1957) and later Brodtkin (1958),

FIGURE 24-11 ■ Lateral chest radiograph of a boy with chondromanubrial pectus carinatum. The short, comma-shaped sternum lacking segmentation is apparent. Arrow is at the tip of the truncated sternum. (From Shamberger RC, Welch KJ: Surgical correction of chondromanubrial deformity [Currarino Silverman syndrome]. *J Pediatr Surg* 23:319–322, 1988. With permission.)

in a technique called the xiphosternopexy, advanced the transected xiphoid and the attached rectus muscles to a higher site on the sternum.^{123,124} This produced posterior displacement of the sternum in younger patients with a flexible chest wall. Howard combined this method with

subperichondrial resection of the costal cartilages and a sternal osteotomy.¹¹⁸ Ravitch reported repair of the chondrogladiolar deformity by resection of costal cartilage in a one- or two-stage procedure, with placement of “reefing” sutures to shorten and posteriorly displace the perichondrium.¹²⁵ A sternal osteotomy was used in one of three cases. Robicsek and associates described repair by subperichondrial resection of costal cartilages, transverse sternal osteotomy, and resection of the protruding lower portion of the sternum.¹²⁶ The xiphoid and rectus muscles were reattached to the new lower margin of the sternum, pulling it posteriorly. In 1973, Welch and Vos reported an approach to these deformities that I continue to use today.¹²⁷

Surgical Technique

The placement of the skin incision, mobilization of the pectoral muscle flaps, and subperichondrial resection of the involved costal cartilage are identical to the method described for pectus excavatum. Management of the sternum is shown in Figure 24-12 for the various deformities. In the chondromanubrial deformity, the costal cartilages must be resected from the second cartilage inferiorly.¹²⁸ A single-limb medium Hemovac drain (Snyder Laboratories, New Philadelphia, OH) is brought through the inferior skin flap, as for excavatum patients, with the suction ports in a parasternal position to the level of the highest resected costal cartilage. The pectoralis muscle flaps and skin flaps are closed. Perioperative antibiotics are used as in pectus excavatum.

Abramson and colleagues have reported a minimally invasive operation for pectus carinatum.¹²⁹ The technique involves placement of a subcutaneous curved steel bar via lateral thoracic incisions. Subperiosteal wires attach small

fixation plates to the ribs laterally, and the convex bar is secured to the small fixation plates with screws. Satisfactory results have been reported. Best results are seen in younger patients with a flexible chest wall, submuscular insertion of the bar, and use of stronger pericostal wire.

Operative Results

Results are overwhelmingly¹³⁰ successful in these patients. In a review of 152 cases, postoperative recovery was generally uneventful.¹¹⁶ Blood transfusions are rarely required, and none has been given in the last 10 years of the report. There is a 3.9% complication rate (Table 24-6). Only three patients have required revision, each having additional lower costal cartilages resected for persistent unilateral malformation of the costal arch.

Nonoperative Correction

Attempts to treat pectus carinatum by orthotic bracing have been reported, beginning in 1992 in Brazil. Evolution of bracing devices has led to an increased success rate, and presently several reports suggest that 65% to

*Two patients required chest tube placement.

FIGURE 24-12 ■ **A**, A single or double osteotomy after resection of the costal cartilages allows posterior displacement of the sternum to an orthotopic position. **B**, The mixed pectus deformity is corrected by full and symmetrical resection of the third to seventh costal cartilages, followed by transverse offset (0- to 10-degree wedge-shaped sternal osteotomy). Closure of this defect achieves both anterior displacement and rotation of the sternum. **C**, The chondromanubrial type of deformity is depicted with a broad, wedge-shaped sternal osteotomy placed through the anterior cortex of the obliterated sternomanubrial junction. Closure of the osteotomy after fracture of the posterior cortex achieves a posterior displacement of the superior portion of the sternum, which is secured only by its attachment to the first rib. The lower portion of the sternum is overcorrected 20 to 35 degrees and is secured in position by strut or suture fixation. (**A** and **B**, From Shamberger RC, Welch KJ: Surgical correction of pectus carinatum. *J Pediatr Surg* 22:48-53, 1987. With permission; **C**, From Shamberger RC, Welch KJ: Surgical correction of chondromanubrial deformity. *J Pediatr Surg* 23:319-322, 1988. With permission.)

80% of children will have resolution with brace treatment alone.^{131-133,134,135} Compliance in using the brace is clearly the rate-limiting factor for success in older patients. Recently efforts have focused on making the brace easy to conceal and comfortable to wear. Bracing strategies that work toward incremental correction over several months have met with better success than previous efforts.^{132,136,137} In teenagers, poor compliance with bracing programs can be addressed by peer pressure at a bracing clinic along the lines of a spina bifida clinic.

This approach works optimally in patients with a symmetrical deformity and has been shown to result in acceptable results even in those with an asymmetrical configuration. The brace varies between institutions, but the primary factor in success of the brace is the patient's compliance with its use.^{138,139,140} Colozza recently reported on a quality-of-life questionnaire survey on patients who had treatment by bracing.^{140a} It revealed that most of the patients were satisfied with their appearance after treatment, experienced minimal pain from the bracing, and would use the brace again. Their self-esteem increased significantly after bracing.

POLAND SYNDROME

In 1841, Poland, while he was a medical student, described congenital absence of the pectoralis major and minor muscles associated with syndactyly.¹⁴¹ Despite a prior report of this entity by Froriep in 1839, the eponym Poland syndrome has been used since 1962, when Clarkson first applied it to a group of similar patients.^{142,143} Subsequent reports have described other components of the syndrome, including absence of ribs, chest wall depression, and abnormalities of the breasts. Each component of the syndrome occurs with variable severity. The extent of thoracic involvement may range from hypoplasia of the sternal head of the pectoralis major and minor muscles with normal underlying ribs to complete absence of the anterior portions of the second to fifth ribs and costal cartilages (Figs. 24-13 and 24-14). Breast involvement is frequent, ranging from mild hypoplasia to complete absence of the breast (amastia) and nipple (athelia) (see Fig. 24-13C).¹⁴⁴ Minimal subcutaneous fat and an absence of axillary hair are additional components of the syndrome. Hand deformities may include hypoplasia of the fingers (brachydactyly) and fused fingers (syndactyly), primarily involving the central three digits. The most severe expression of the anomaly, mitten or claw deformity (ectromelia), is rare.^{143,145} Extensive classification systems of the associated hand anomalies has been developed.¹⁴⁶ Poland syndrome may also occur in combination with Sprengel deformity, in which there is decreased size, elevation, and winging of the scapula.

Poland syndrome is present at birth and has an estimated incidence of 1 in 30,000 to 1 in 32,000.^{147,148} Abnormalities of the breast can be defined at birth by absence of the underlying breast bud and the hypoplastic nipple, which is often superiorly displaced. The cause of Poland syndrome is unknown. Bouvet and associates proposed hypoplasia of the ipsilateral subclavian artery as the origin of this malformation, but, as noted by David,

decreased blood flow to the extremity may be the result of decreased muscle mass of the hypoplastic limb rather than its cause.^{149,150} Although some forms of syndactyly are autosomal dominant traits, a similar pattern has not been demonstrated in patients with Poland syndrome, which is generally sporadic. Multiple cases within a family are rare although its appearance in one of two identical twins was described.¹⁵¹⁻¹⁵⁴ Poland syndrome is associated with a second rare syndrome, the Möbius syndrome: bilateral or unilateral facial palsy and abducens oculi palsy. Nineteen such cases have been identified, but a unifying cause is lacking. Familial occurrence of these two syndromes was reported.^{155,156} An unusual association between Poland syndrome and childhood leukemia has also been reported.^{157,158}

The Boston Children's Hospital experience with Poland syndrome (1970 to 1987) included 41 children and adolescents, of whom 21 were males.¹⁵⁹ The lesion was right sided in 23 patients, left sided in 17 patients, and bilateral in 1 patient. Hand anomalies were noted in 23 (56%) and breast anomalies in 25 (61%). In 10 children, the underlying thoracic abnormality required reconstruction, and in 3 children, rib or cartilage grafts were needed for complete repair.

Surgical Repair

Assessment of the extent of involvement of the various musculoskeletal components is critical for optimal thoracic reconstruction. If the deformity is limited to the sternal component of the pectoralis major and minor muscles without underlying chest wall deformity, there is little functional deficit and repair is unnecessary, except to facilitate breast augmentation in females (see Fig. 24-14). If the underlying costal cartilages are depressed or absent, repair must be considered to minimize the concavity, to eliminate the paradoxical motion of the chest wall if ribs are absent, and in girls to provide an optimal base for breast reconstruction. Ravitch reported correction of posteriorly displaced costal cartilages by unilateral resection of the cartilages; a wedge osteotomy of the sternum allowing rotation of the sternum; and fixation with Rehbein struts and Steinmann pins.¹⁰⁰ I have achieved suitable repair in most cases with bilateral costal cartilage resection and an oblique osteotomy, which corrects both sternal rotation and posterior displacement, as in the patients with mixed pectus carinatum and excavatum deformity (Fig. 24-15). The sternum is then displaced anteriorly and is supported with a retrosternal strut, which allows correction of the posteriorly displaced costal cartilages. An unappreciated carinate deformity is often present on the contralateral side, which accentuates the ipsilateral concavity (see Fig. 24-14B).

Absence of the medial portion of the ribs can be managed with split rib grafts taken from the contralateral side. These must be secured to the sternum medially and to the "dagger point" ends of the hypoplastic ribs laterally. The grafts can be covered with a prosthetic mesh if needed for further support. In these cases, it must be remembered that there is little tissue present between the endothoracic fascia and the fascial remnants of the pectoral muscles. Soft tissue coverage of the area can be

FIGURE 24-13 ■ **A**, Muscular 15-year-old boy with Poland syndrome with loss of the left axillary fold owing to absence of the pectoralis major muscle. He has an orthotopic sternum and normal cartilages. He compensates adequately for loss of the pectoralis major and minor muscles. Surgery is not indicated in males with these findings. **B**, Eight-year-old boy with Poland syndrome and more extensive thoracic involvement. The pectoralis major and minor muscles and the serratus to the level of the fifth rib are absent. There is sternal obliquity, and the third to fifth ribs are aplastic, ending at the level of the nipple. The corresponding costal cartilages are absent. The endothoracic fascia lies beneath a thin layer of subcutaneous tissue. Note the hypoplastic nipple and ectromelia of the ipsilateral hand, the most severe malformation of the hand associated with Poland syndrome. **C**, Fourteen-year-old girl with Poland syndrome. Note the high position of the right nipple, amastia, sternal rotation, and depressed right chest. The anterior second to fourth ribs and cartilages were missing. Breast augmentation will be required after the ipsilateral breast achieves full growth.

augmented with transfer of a latissimus dorsi muscle flap. This is particularly helpful in girls who will require breast augmentation.¹⁶⁰⁻¹⁶² Flap rotation is seldom, if ever, required in boys and has the disadvantage of adding a second posterior thoracic scar and decreasing the strength of the latissimus dorsi muscle.

Customized silicone prostheses can be used to correct both the chest wall depression and the absence of the breast.¹⁶³ Other recent innovations in repair include use

of Surgisis and a “swinging rib” or of a vertical expandable prosthetic rib system.¹⁶⁴

STERNAL DEFECTS

Sternal defects are rare compared with pectus excavatum and pectus carinatum, yet they have received a great deal of attention in the medical literature because of their

FIGURE 24-14 ■ The spectrum of thoracic abnormality seen in Poland syndrome. **A**, Most frequently, an entirely normal thorax is present, and only pectoral muscles are absent. **B**, Depression of the involved side of the chest wall, with rotation and often depression of the sternum. A carinate protrusion of the contralateral side is frequently present. **C**, Hypoplasia of ribs on the involved side but without significant depression may be seen. It usually does not require surgical correction. **D**, Aplasia of one or more ribs is usually associated with depression of adjacent ribs on the involved side and rotation of the sternum. (From Shamberger RC, Welch KJ, Upton J, III: Surgical treatment of thoracic deformity in Poland syndrome. *J Pediatr Surg* 24:760–765, 1989. With permission).

dramatic presentation and often fatal outcome. Deformities resulting from failure of ventral fusion of the sternum can be divided into four groups: (1) cleft sternum, (2) thoracic ectopia cordis, (3) thoracoabdominal ectopia cordis, and (4) cervical ectopia cordis. The heart is in a normal position in cleft sternum but is displaced in the other three entities. In thoracic ectopia cordis, the heart protrudes anteriorly and there are no tissues covering the heart. In cervical ectopia cordis, the protrusion is even more pronounced, and the heart is often fused with the head. In thoracoabdominal ectopia cordis, the heart is covered but often displaced into the abdomen through a defect in the diaphragm.

Cleft Sternum

An infant with cleft sternum has a complete or partial separation of the sternum but a normally positioned intrathoracic heart. This deformity results from failure of fusion of the sternal bars, which should occur approximately the eighth week of gestation. In all such cases, despite the sternal separation, normal skin coverage is present, with an intact pericardium and a normal diaphragm. Abdominal wall defects such as omphalocele do not occur in these children. The condition causes few functional problems. A dramatic increase in the protrusion of the deformity occurs with crying or Valsalva maneuver. The sternal defects described in 109 cases are summarized in Table 24-7.¹⁶⁵ The cleft involves primarily the upper sternum, whereas patients with thoracic or thoracoabdominal ectopia cordis have clefts primarily of the lower sternum.

TABLE 24-7 Sternal Defects Reported in 109 Cases of Cleft Sternum

	Number of Cases
Upper cleft	46
Upper cleft to xiphoid	33
Complete cleft	23
Lower defect with manubrium or midsegment intact	5
Central (skin ulceration noted in only three cases) defect with manubrium and xiphoid intact	2

From Shamberger RC, Welch KJ: Sternal defects. *Pediatr Surg Int* 5:156–164, 1990. With permission.

The second distinction between cleft sternum and the other sternal defects is that children with cleft sternum rarely have intrinsic congenital heart disease. An unexplained association does exist, however, between cleft sternum and cervicofacial hemangiomas, which were reported in 14 cases since the first description of this association by Fischer in 1879.¹⁶⁶

Surgical Repair

Maier and Bortone accomplished the first primary repair of cleft sternum in 1949 in a 6-week-old infant.¹⁶⁷ The flexibility of the newborn chest allows approximation of the sternal bars without producing cardiac compression (Fig. 24-16). A summary of the reported repairs for cleft sternum in 69 cases is shown in Table 24-8.

FIGURE 24-15 ■ **A**, A transverse incision is placed below the nipple lines and, in females, in the inframammary crease. **B**, Schematic depiction of the deformity, with rotation of the sternum, depression of the cartilages of the involved side, and carinate protrusion of the contralateral side. **C**, In patients with aplasia of the ribs, the endo-thoracic fascia is encountered directly below the attenuated subcutaneous tissue and pectoral fascia. The pectoral muscle flap is elevated on the contralateral side and the pectoral fascia, if present, on the involved side. Subperichondrial resection of the costal cartilages is then carried out, as shown by the **bold dashed lines**. Rarely, this must be carried to the level of the second costal cartilages. **D**, A transverse, offset, wedge-shaped sternal osteotomy is created below the second costal cartilage. Elevation of the sternum with a retrosternal strut corrects both the posterior displacement and the rotation of the sternum. **E**, In patients with rib aplasia, split rib grafts are harvested from the contralateral fifth or sixth rib and then secured medially with wire sutures into previously created sternal notches and with wire to the native ribs laterally. Ribs are split, as shown, along their short axis to maintain maximum mechanical strength. (From Shamberger RC, Welch KJ, Upton J, III: Surgical treatment of thoracic deformity in Poland's syndrome. *J Pediatr Surg* 24:760-765, 1989. With permission.)

FIGURE 24-16 ■ **A**, Repair of bifid sternum is best performed through a longitudinal incision extending the length of the defect. **B**, Directly beneath the subcutaneous tissues the sternal bars are encountered, with pectoral muscles present lateral to the bars. **C**, The endothoracic fascia is mobilized off the sternal bars posteriorly with blunt dissection to allow safe placement of the sutures. Approximation of the sternal bars may be facilitated by excising a wedge of cartilage inferiorly. **D**, Closure of the defect is achieved with 2-0 Tevdek or PDS (Ethicon, Sommerville, NJ) sutures. (From Shamberger RC, Welch KJ: Sternal defects. *Pediatr Surg Int* 5:156–164, 1990. With permission.)

Sabiston reported reconstruction of cleft sternum using multiple oblique chondrotomies.¹⁶⁸ The chondrotomies increase the chest wall dimensions and flexibility. The technique is useful in older infants and children with a less flexible chest and a wide defect. Meissner described a variation of repair in which the cartilages are divided laterally and swung medially to cover the defect.¹⁶⁹ Autologous grafts of costal cartilage, split ribs, and segments of the costal arch have been used since Burton first repaired this defect with a portion of the costal arch.¹⁷⁰ Repairs with prosthetic material are far less satisfactory because of the risks of infection and the inability of these tissues to grow with the child. Most authors now recommend treatment of cleft sternum in the newborn period, when simple direct closure is possible without the use of prosthetic materials or grafts.

Ectopia Cordis

Although treatment of isolated cleft sternum is routinely successful, surgical repair of ectopia cordis, particularly

thoracic ectopia cordis, has a high mortality rate. The lethal factor in thoracic ectopia cordis and cervical ectopia cordis is the extrathoracic location of the heart, which makes tissue coverage difficult. In thoracoabdominal ectopia cordis (the Cantrell pentalogy), the major impediment to survival is the high incidence of intrinsic congenital heart disease.¹⁷¹

Cause

The cause of thoracic ectopia cordis and thoracoabdominal ectopia cordis is much debated. Some consider these anomalies to be the result of disruption of the amnion and possibly disruption of the chorionic layer or yolk sac as well.¹⁷²⁻¹⁷⁵ This disruption occurs during the third or fourth week of gestation at a time when cardiac chamber formation is occurring rapidly. This timing may account for the high incidence of abnormal cardiac development. Von Praagh (personal communication, 1987) has the intriguing notion, based on embryology studies by Patten and Bremer, that acute hyperflexion of the craniocervical segment of the embryo pins the heart down in the extrathoracic position with the submental cardiac apex.^{176,177} The abnormal fetal configuration produced by oligohydramnios may persist to delivery and oppose traction by the gubernaculum cordis, which normally pulls the cardiac apex into caudal alignment. Chromosome abnormalities have been reported.¹⁷⁸⁻¹⁸⁰

Thoracic Ectopia Cordis

Thoracic ectopia cordis is one of the most dramatic occurrences in the delivery room (Fig. 24-17). The naked beating heart is external to the thorax. Clearly visible are the atrial appendages, coronary vasculature, and cephalic orientation of the cardiac apex. The gubernaculum cordis initially extends to the supraumbilical raphe. Thoracic ectopia cordis was first reported by Stensen in 1671.¹⁸¹ Stensen's report was later translated by Willis.¹⁸² Stensen identified the four components of the tetralogy of Fallot in this patient with thoracic ectopia cordis. Cardiac anomalies are unusually frequent in thoracic ectopia

FIGURE 24-17 ■ An infant with thoracic ectopia cordis with no abdominal wall defect. The cardiac apex is cephalad. Any movement of the heart resulted in bradycardia and arrest. The patient had complex tetralogy of Fallot.

cordis. Table 24-9 lists the associated cardiac anomalies reported up to 1990. Only 4 of 75 cases had no intrinsic cardiac anomalies.

Infants with thoracic ectopia cordis are severely deficient in the midline somatic tissues that normally cover the heart. Many attempts at primary closure fail because of the inability to mobilize adequate tissues for coverage. An abdominal defect is often present as well. Recent computed tomogram evaluation by Haynor and associates also shows reduced intrathoracic volume in these infants.¹⁸³ Most allegedly successful repairs have been not of true thoracic ectopia cordis but, rather, of thoracoabdominal ectopia cordis. Cutler and Wilens first attempted repair in 1925 by skin flap coverage but failed because of cessation of cardiac function, presumably from compression of the heart.¹⁸⁴ Only 3 survivors of more than 29 attempts have been recorded (Table 24-10).

The first successful repair of ectopia cordis was achieved by Koop in 1975 and was reported by Saxena.¹⁸⁵ An infant with a normal heart had skin flap coverage at 5 hours of age, with inferior mobilization of the anterior attachments of the diaphragm. The sternal bars were 2 inches apart and could not be approximated primarily without cardiac compression and compromise. When the infant was 7 months old, an acrylic resin of Dacron and Marlex mesh was inserted to close the sternal cleft, followed by primary skin closure. Necrosis of the skin flaps complicated the postoperative course with infection of the prosthetic material, which was later removed. This child was well at 20-year follow-up.

Successful closure in two other infants is reported. Dobell and associates also achieved closure in two

stages.¹⁸⁶ Skin flap coverage was provided for the newborn. Rib strut grafts were placed over the sternal defect at 19 months of age and covered with pectoral muscle flaps. The pericardium was divided from its anterior attachments to the chest wall, allowing the heart to fall back partially into the thoracic cavity. Only Amato and colleagues achieved complete coverage of the heart in one stage.¹⁸⁷ The unifying theme of successfully managed cases is mobilization of adequate soft tissue to cover the heart in its extrathoracic location and avoiding attempts to return the heart to an orthotopic location. Of note, in the successful cases, intrinsic cardiac lesions and associated abdominal defects were absent. These are the characteristics that most distinguish the successes from the failures, rather than any differences in surgical techniques. Coverage of the heart with autologous tissues, whether by flap rotation or bipedicle flaps, generally produces excessive compression on the heart, which limits cardiac output either by kinking outflow vessels or by impeding cardiac filling. In most cases, attempts are abandoned in the operating room because of severe impairment of cardiac function. In patients who are repaired with autologous tissue grafts (bone or cartilage) or synthetic materials, infection and extrusion of the graft invariably occur. Ultimate success with this lesion will be achieved only by accomplishing tissue coverage of the heart that avoids posterior displacement into an already limited thoracic space. This will require use of tissues from sites distant from the chest wall or engineered tissue materials. Severe intracardiac defects associated with thoracic ectopia cordis in most cases also limit survival. The only recent advancement in management of this lesion has been early ultrasonographic diagnosis, including definition of the intracardiac lesion and termination of the pregnancy, if acceptable to the parents.^{188,189}

Abdominal wall defects are also frequent in these patients, including an upper abdominal omphalocele or diastasis recti and, rarely, eventration of the abdominal viscera (Fig. 24-18). Associated abdominal wall defects are summarized in Table 24-11. The presence of abdominal defects should not, however, lead to classification of these lesions as thoracoabdominal ectopia cordis. This term should be reserved for those infants in whom the heart is covered at birth.

Thoracoabdominal Ectopia Cordis (Cantrell Pentalogy)

In thoracoabdominal ectopia cordis, the heart is covered by an omphalocele-like membrane or thin skin, which is

FIGURE 24-18 ■ Infant with thoracic ectopia cordis (arrow) and eventration of the abdominal viscera. (From Shamberger RC, Welch KJ: Sternal defects. *Pediatr Surg Int* 5:156–164, 1990. With permission.)

often pigmented. The sternum is generally cleft inferiorly, and the heart lacks the severe anterior rotation present in thoracic ectopia cordis. An early report of this lesion by Wilson in 1798 clearly defined the associated somatic defects of the abdominal wall, diaphragm, and pericardium (Fig. 24-19), as well as the intrinsic cardiac anomalies. This entity was subsequently reviewed by Major in 1953 and Cantrell and associates in 1958.^{171,190} It is now frequently called Cantrell pentalogy, although it was described long before Cantrell's relatively recent review. The five essential features of thoracoabdominal ectopia cordis are a cleft lower sternum, a half moon-shaped anterior diaphragmatic defect resulting from lack of development of the septum transversum, absence of the parietal pericardium at the diaphragmatic defect,

FIGURE 24-19 ■ Newborn male with thoracoabdominal ectopia cordis. The head is to the left. Note the epigastric omphalocele extending superior to the umbilicus. The cardiac apex was visible below the costal arch just at the superior aspect of the omphalocele.

omphalocele (Table 24-12), and, in most patients, an intrinsic cardiac anomaly (Table 24-13; see Fig. 24-19). A left ventricular diverticulum occurs with surprising frequency in patients with this anomaly. In many cases, the diverticulum protrudes through the diaphragmatic and pericardial defects into the abdominal cavity.

Successful repair and long-term survival are more frequent in thoracoabdominal ectopia cordis than in thoracic ectopia cordis. Arndt attempted the first repair in 1896, but return of the heart to the thoracic cavity resulted in death.¹⁹¹ Wieting performed the first successful surgical repair in 1912.¹⁹² He achieved primary closure of the diaphragm and abdominal wall fascia but ignored the ventricular diverticulum. Initial surgical intervention must address the skin defects overlying the heart and abdominal cavity. Primary excision of the omphalocele with skin closure avoids infection and mediastinitis, although several cases have been successfully managed by local application of topical astringents, thus allowing secondary epithelialization to occur. Several early cases, as in that of Cullerier in 1806, document the long-term viability of individuals with thoracoabdominal ectopia cordis with intact skin coverage despite the abnormal location and coverage of the heart.¹⁹³

Advances in cardiac surgery now allow correction of the intrinsic cardiac lesions, which were previously fatal.

An aggressive approach to repair in infants with thoracoabdominal ectopia cordis is appropriate. Repair of the abdominal wall defect or diastasis has been achieved by primary closure or prosthetic mesh (Table 24-14). Primary closure of the thoracoabdominal defect may be difficult to achieve because of the wide separation of the rectus muscles and their superior attachment to the costal arches. A resorbable poly-L-lactic polyglycolic acid plate and other prosthetic materials have been used for this repair.¹⁹⁴ Complete repair of the intracardiac defect is best performed before placement of prosthetic mesh overlying the heart. Repair of the abdomen and chest wall is important primarily for mechanical protection of the heart and abdominal viscera. Early diagnosis by prenatal ultrasound has not altered the surgical approach or overall mortality of this lesion. Three cases in the Boston Children's Hospital series had severe pulmonary hypoplasia, which was lethal in two, a previously unreported association.¹⁶⁵

THORACIC DEFORMITIES IN DIFFUSE SKELETAL DISORDERS

Asphyxiating Thoracic Dystrophy (Jeune Disease)

In 1954, Jeune and colleagues described a newborn with a narrow rigid chest and multiple cartilage anomalies.¹⁹⁵ The patient died of respiratory insufficiency early in the perinatal period. Subsequent authors have further characterized this form of osteochondrodystrophy, which has variable degrees of skeletal involvement. It is inherited in an autosomal recessive pattern and is not associated with chromosomal abnormalities. Its most prominent feature is a narrow, bell-shaped thorax and protuberant abdomen. The thorax is narrow in both transverse and sagittal axes and has little respiratory motion because of the horizontal direction of the ribs (Fig. 24-20). The ribs are short and wide, and the splayed costochondral junctions barely reach the anterior axillary line. The costal cartilage is abundant and irregular, like a rachitic rosary. Microscopic examination of the costochondral junction demonstrates disordered and poorly progressing endochondral ossification, resulting in decreased rib length.

Skeletal abnormalities associated with this syndrome include short stubby extremities with relatively short and wide bones. The clavicles are in a fixed and elevated position, and the pelvis is small and hypoplastic, with square iliac bones.

FIGURE 24-20 ■ Jeune disease (asphyxiating thoracic dystrophy). **A**, Anteroposterior radiograph shows short horizontal ribs and narrow chest. **B**, Lateral radiograph demonstrates that the short ribs end at the midaxillary line. Abnormal flaring at the costochondral junctions is also present. The patient died of progressive respiratory insufficiency at 1 month of age. There was no surgical intervention. Postmortem examination revealed alveolar hypoplasia.

FIGURE 24-21 ■ Chest radiograph of an infant with spondylothoracic dysplasia. Severe abnormality of the spine is apparent, with multiple alternating hemivertebrae producing a crablike configuration to the ribs.

The syndrome has a variable extent of pulmonary impairment. Although the initial cases reported resulted in neonatal deaths, subsequent reports by Kozlowski and Masel and others have documented that infants can survive for longer intervals of time with this syndrome.¹⁹⁶ The pathologic findings in autopsy cases reveal a range of abnormal pulmonary development. In most cases, the bronchial development is normal and there are fewer alveolar divisions, as described by Williams and associates.¹⁹⁷

Spondylothoracic Dysplasia (Jarcho-Levin Syndrome)

Spondylothoracic dysplasia is an autosomal recessive deformity with multiple vertebral and rib malformations, described by Jarcho and Levin in 1938.¹⁹⁸ Infants and children with this syndrome have multiple alternating hemivertebrae in most, if not all, of the thoracic and lumbar spine. The vertebral ossification centers rarely cross the midline, although bone formation is normal. Multiple posterior fusions of the ribs and remarkable shortening of the thoracic spine result in a crablike appearance of the ribs on the chest radiograph (Fig. 24-21).

The thoracic deformity is secondary to the spine anomaly, which results in close posterior approximation of the origin of the ribs. Although most infants with the entity succumb before 15 months of age, as reviewed by Roberts and colleagues, no surgical efforts have been proposed or attempted.¹⁰³ One third of patients with this syndrome have associated malformations, including congenital heart disease and renal anomalies. Heilbronner and Renshaw have reported its occurrence primarily in Puerto Rican families (15 of 18 cases).¹⁹⁹

SUMMARY

Chest wall tumors are relatively rare tumors that include a variety of soft tissue and bone tumors. Although rarely seen by physicians practicing in a nonspecialized practice, patients who have these tumors need careful consideration because the evaluation and management are varied and full of pitfalls. Some of the tumors need no therapy, others need radical surgical resection, some need preoperative chemotherapy or radiation therapy, and reconstruction is always an important issue in the planning of resection. Even a simple biopsy of a chest wall tumor is important, because improperly performed biopsy can make future treatment more difficult. In general, the management of chest wall tumors should be referred to a specialized center for optimal outcome.

Ostias Aimaz is credited with the first chest wall resection in 1778.¹ As surgical and anesthetic techniques evolved, therapy for chest wall tumors evolved. O. T. Clagett, at the Mayo Clinic in Rochester did much of the initial pioneering work and published his findings in 1957.² Drs. Pairolero and Arnold subsequently built on this foundation and advanced the surgical resection and reconstruction of chest wall tumors.³⁻⁶

Because the lesions are rare, most (if not all) of the data on management of these patients are based on retrospective series. There are no randomized trials; thus much of what we know is not evidence based but rather based on trial and error. Most of the larger series are from specialized cancer centers such as the MD Anderson

Cancer Center, Memorial Sloan Kettering Hospital, and the Mayo Clinic, but in recent years there has been an effort to pool information from many institutions to improve knowledge.^{5,7-10}

Metastatic lesions are the most common chest wall tumor, and their management depends on the status of the primary disease.¹¹ Occasionally, metastatic disease should be resected or radiated for symptom control or cure. Infections of the chest wall could also be considered “tumors.” This chapter, however, will deal with primary chest wall tumors.

PRESENTATION AND EVALUATION

History

As with most problems in medicine, a careful history and physical examination can help establish a diagnosis and prevent errors. Although approximately 20% of patients with primary chest wall tumors have their tumors discovered as incidental findings, most present with a mass or pain. Patients should be questioned about when the pain started, where it is located, what the intensity of the pain is, and what makes it better or worse. Pain usually, but not always, implies a malignant lesion. Severe pain that requires narcotics for relief should alert the clinician that the tumor might infiltrate nerves. When a mass is present,

the patient should be questioned about when it was first discovered and questions asked to determine its growth rate. A history of fever, weight loss, and malaise should be sought, which could help narrow the diagnostic possibilities.

A history of trauma to the area should be elicited, because there seems to be a correlation between trauma to an area and the development of a sarcoma. The history should include data about prior cancers, radiation therapy, operations, infections, travel, and hereditary disease (e.g. Gardner or von Recklinghausen disease).

Physical Examination

After the history, a physical examination should be completed with emphasis on the lesion in question. If a mass is present, it should be palpated to see if it hard or soft, mobile or fixed, and tender or not tender. Its location should be carefully documented. It is often helpful to palpate the lesion with the patient in the same position he or she will be in for surgery, which may prevent any intraoperative surprises. The extremities should be moved to see if the mass moves with any arm movements. Lymphadenopathy, if present, should be palpated and other lumps, scars, or tender spots examined.

Imaging

Chest Radiographs

Although not very sensitive, a plain chest radiograph (CXR) may be the initial radiograph that discovers the chest wall lesion. Old CXRs should be obtained and examined in an attempt to establish a growth rate of the lesion. Rib films can be used to help determine bony erosion or lytic lesions, but computed tomography (CT) is much more sensitive. The CT gives information about the location of the lesion and its relationship to the rib, soft tissue, pleura, and any vascular structures or nerves in the local area (Fig. 25-1). It is very helpful for surgical planning as well.¹² Careful viewing of the CT will usually narrow the diagnostic possibilities and in some patients is diagnostic.¹³ Examples include fibrous dysplasia, which has a characteristic lytic appearance with an intact cortex; Ewing sarcoma, which elevates the periosteum (Fig. 25-2) and leads to a radiographic sign known as Codman triangle (this is a pseudotriangle because it is only two sided: the original bone and the elevated cortex); and the characteristic stippled or ring-and-arc calcification seen in a chondrosarcoma.¹⁴ Magnetic resonance imaging (MRI) is useful as well because it can delineate between soft tissue, bone, nerve, or vascular structures in a multiplanar fashion (Fig. 25-3).¹⁵ Occasionally MRI can lead to a specific diagnosis such as in the case of myxoid chondrosarcoma where the lesion will have markedly high signal intensity on T2-weighted images secondary to the myxoid component.¹²

Proton emission tomography (PET) and bone scanning can be used to search for metastatic disease. The standard uptake value (SUV) obtained in PET may help with prognosis, but there is not enough data to support this supposition. It is also not known whether obtaining

FIGURE 25-1 ■ CT scan of a right anterior chest wall mass.

FIGURE 25-2 ■ CT scan of a right posterior Ewing tumor.

a PET on all patients with a malignant primary chest wall is cost effective. At present, if there is suspicion of a metastatic deposit, obtaining a PET seems like a reasonable option. PET is not a method to definitively determine if a mass is malignant or benign.

Preoperative Evaluation

Because primary chest wall tumors are usually treated with surgery, preoperative evaluation of other medical issues is warranted. The cardiovascular system should be investigated with regard to possible ischemic heart disease

FIGURE 25-3 ■ MRI of the right anterior chest wall mass seen in Figure 25-1. The MRI is often a better way to delineate the tumor from surrounding tissue.

and pulmonary dysfunction. Pulmonary function testing should be done to determine the risks of removing a portion of the chest wall and its deleterious effects on pulmonary mechanics. If patients are smoking, they should stop. This will reduce the risk of pulmonary infections and improve the blood flow to any tissue flaps that are necessary to cover the resection. As in all surgery, diabetes should be under control. Patients should also be counseled on postoperative physical therapy that may be necessary.

SURGICAL MANAGEMENT

Preoperative Biopsy

One of the major problems with primary chest wall lesions is how to obtain a tissue diagnosis.¹⁶ If biopsy is not performed correctly, future therapy and even survival can be jeopardized. If the lesion is small (i.e., <3 cm) and in a favorable location (lateral chest wall away from vital structures), an excisional biopsy can be undertaken.¹⁷ Because pathologic examination often requires overnight decalcification, frozen section may not be available. If the pathology cannot be determined based on excisional biopsy, the incision should be closed with careful attention to prevention of a postoperative hematoma, which could spread potentially malignant cells into the surrounding area. The incision for the biopsy should also be placed with consideration for further resection, because if the pathology returns malignant, the biopsy site should be excised. Extensive flaps or dissection should be avoided in the initial biopsy, because cure rate is related to margins of resection.

For large tumors (i.e., ≥ 3 cm) or tumors located in a critical area (near great vessels), a core needle biopsy can be done. Fine-needle aspiration (FNA) is not useful except when a metastatic lesion is suspected because FNA limits the amount of histologic tissue and tissue architecture.¹⁷ A core needle biopsy is approximately 95% accurate.¹⁸ Even though pathology is not 100% accurate, between a good history, physical examination, and radiographic imaging, the diagnosis should be highly reliable.

Anesthetic Considerations

Chest wall resections are usually done under general endotracheal anesthesia. If lung resection is anticipated or special exposure is required, a double-lumen tube can be used, but usually single-lumen anesthesia will suffice. Pain control postoperatively is accomplished with epidural analgesia and supplemented with parenteral narcotics and nonsteroidal anti-inflammatory medications. The routine use of standard perioperative antibiotics (one dose of a cephalosporin just prior to the incision and one dose postoperatively) has been clearly established and should be used. Control of glucose in all patients, but especially in diabetics, has been shown to lower postoperative complication rates.¹⁹

Intraoperative Considerations

Resection of the mass should be complete, the margin of resection depending on the histologic type of the tumor and its location on the chest wall. The initial resection is the best, and perhaps only, chance for a curative operation as reoperations for recurrent tumors are unlikely to be curative. The resection should be en bloc, including overlying skin, soft tissue, and muscle and with an adequate margin. No randomized trials are available to help determine the optimal margin; only retrospective series are available to determine the extent of resection. In 1986, King and colleagues, from the Mayo clinic, published their series of 90 patients who underwent chest wall resection for primary chest wall tumors.⁵ Approximately 80% of the patients had a malignant lesion; one quarter of these classified as a malignant fibrous histiocytoma (now called pleomorphic sarcoma), one quarter chondrosarcoma, and one half a mixture of other lesions. The researchers found that patients that had a margin of at least 4 cm had a lower recurrence rate than those with a lesser margin. They also recommended resecting the adjacent marrow cavity (rib or sternum) if the tumor could invade into the marrow. In a separate study from the same institution that just included 96 patients with primary chest wall chondrosarcoma, McAfee and coworkers reported a statistically significant survival advantage for resections with at least a 4-cm margin.²⁰ For tumors that are too close to vital structures for the recommended margin, a compromise must be made. However, fear of reconstruction should not limit the extent of resection. With modern reconstructive techniques, many options are available and cure should not be compromised. Thoracoscopic techniques have been used to resect these types of lesions, but the data on long-term outcome are limited.²¹

Reconstruction

After wide excision, the goals of reconstruction are to replace the rigid chest wall to provide protection to the underlying viscera and restore the mechanics of respiration.²² In the noninfected patient, the rigid chest wall can be reconstructed with a variety of material. Sheets of 2-mm-thick polytetrafluoroethylene (Gore-Tex, W. L. Gore and Associates) are the easiest to use for chest wall reconstruction. The sheets are sewn into the chest wall with nonabsorbable sutures and then covered with soft tissue. Other options include a methylmethacrylate Marlex mesh sandwich, which allows placing curved shapes into the chest wall, which can be useful for larger defects.²³ Polypropylene (Prolene, Ethicon, Inc.) or polyglactin (Vicryl, Ethicon, Inc.) mesh can also be used for bony chest wall reconstruction.²⁴

Soft tissue reconstruction is required to cover the defect. If the defect is small, local tissue can be elevated and primarily closed over the defect. For larger defects, muscle or musculocutaneous flaps are used to cover the defect. These include latissimus dorsi, pectoralis major, rectus abdominis, serratus anterior, and external oblique flaps. In rare circumstances, a free flap is required to cover the defect if no local rotational flaps are available. Omentum can also be brought into the area, if necessary, to provide a vascular bed for tissue ingrowth. Series by Arnold and Pairolero are excellent resources for details about chest wall reconstruction after resection.^{3,4,25-27}

Postoperative Care

Postoperative care should be routine in most chest wall resections unless the amount of chest wall removed was so large that it severely compromises pulmonary mechanics. If ventilation mechanics are difficult postoperatively, mechanical ventilation may be necessary, but this is quite unusual. Even complete sternal resections for tumors do not commonly require prolonged ventilator support. Aggressive chest physiotherapy and early ambulation are important aspects of care, although randomized trials proving their efficacy are limited. Appropriate analgesia is important for early ambulation and deep breathing and coughing. If the pleural space was entered during the resection, chest tubes can be removed when the drainage is below 300 mL in a 24-hour period and no air leak is present.

If infection occurs and foreign material was used for reconstruction, the foreign material will need to be removed. A thick fibrous layer forms under the material within the first several weeks, so removal will not result in an open pneumothorax. The foreign material can be removed, the soft tissue replaced, and the patient treated with appropriate antibiotic. If the long-term cosmetic result is unsatisfactory, a subsequent reconstruction can be undertaken later, after the infection has fully resolved.

Follow-up

Patients should return for follow-up several weeks after discharge from the hospital to be sure they are healing

properly, their pain is under control, and any questions they have are answered. Additional therapy, such as radiation or chemotherapy, depends on the margins of resection and the histology of the tumor. Patients should be followed long term to look for signs of recurrence. Periodic MRIs or CTs are useful to image the resected area after surgery. A yearly interval seems reasonable, but no standard currently exists.

SPECIFIC LESIONS

Benign

Osteochondroma

The most common benign chest wall tumor is an osteochondroma. This type of chest wall tumor occurs three times more frequently in males than females. Osteochondromas are cartilage-capped bony projections arising on the external surface of bone that contains a marrow cavity that is continuous with that of the underlying bone.²⁸ Approximately 85% of these tumors arise as a solitary event with no hereditary link. Hereditary multiple osteochondromas (HMOs) is a disorder caused by mutation in the exostosis (multiple)-1 (EXT1) or exostosis (multiple)-2 (EXT2) gene and is inherited in an autosomal dominant fashion.²⁹ Patients with HMOs may have multiple lesions.

These lesions can present as a painless mass or a pathologic fracture, or they may be found incidentally on a chest roentgenogram. They have a characteristic radiographic appearance, "a sessile or stalked exostosis whose pedicle merges with the adjacent cortex, a peripheral rim of calcification and stippled calcification within the tumor mass."³⁰

The lesions can be safely observed with serial imaging. Indications for resection include enlargement, concern about the accuracy of the diagnosis, and development of pain. Occasionally the lesions can impinge on the spine or vascular system and require resection for relief. Resection requires only a negative margin.

Chondroma

Chondroma is a benign cartilaginous tumor that typically occurs at the costocartilage junction on the chest wall. It is most commonly seen in 20- to 30-year-olds and makes up approximately 20% to 30% of the benign chest wall tumors. The history of the lesion is usually a slowly enlarging nonpainful mass that the patient has noticed recently. On palpation it is fixed to the bony chest wall and nontender. Radiographically it appears as a soft tissue periosteal mass with a thin cortex but sclerotic. Calcification is often present and can be in a diffuse or stippled pattern. Histologic analysis shows mature hyaline cartilage cells with foci of myxoid degeneration and calcium.

Chondroma is difficult to differentiate from its malignant counterpart, chondrosarcoma, so tumors of this type should be resected to establish a diagnosis. Resection is usually straightforward with a 2-cm margin sufficing. Recurrence, if benign, is uncommon.

Fibrous Dysplasia

Fibrous dysplasia is thought to be a developmental disorder in which normal bone is replaced by fibrous stroma and immature bone. It occurs most commonly in 20- to 30-year-olds and is equally distributed between men and women. The lesion presents as a painless mass and in over 80% of the patients is a solitary lesion. Multiple lesions can occur as part of the McCune-Albright syndrome, which includes café au lait spots, endocrine disorders, short stature, and precocious puberty.³¹ The radiographic appearance shows a central fibrous area in the rib with a thinned cortex and a lytic component. The lesion can have the appearance of “soap bubbles” or ground glass. Histologic analysis reveals irregular shaped speckles of bone cells that often have bizarre shapes. They have been described as “Chinese characters” by some to signify the odd appearance.³¹ Treatment is observation, unless the lesion becomes painful or enlarges. Resection with negative margins is curative.

Eosinophilic Granuloma

These tumors are a disorder of the lymphoreticular system and not really a true bone tumor. They involve proliferation of histiocytes, Langerhans cells, giant cells, and eosinophils. They can affect the rib or the sternum with a peak incidence in 5- to 15-year-old patients. They present with pain, fevers, and an isolated tender mass in the chest wall. CT scan shows the lesion destroys the cortex, makes new subperiosteal bone, and can mimic osteomyelitis or malignancy. Core biopsy shows Birbeck granules on electron microscopy.³² Treatment is local excision for diagnosis or relief of symptoms. Alternatively, if the diagnosis is known, intralesional or systemic corticosteroid or low-dose radiation can be used.³³

Hemangioma

Hemangiomas are thought to be congenital vascular malformations that occur in the rib or intercostal space. They may be related to trauma, hormonal imbalance, or liver disease, but most are thought to be congenital. They appear, similar to other benign chest wall tumors, as a painless mass, usually in children. The radiographic appearance on CXR shows the shadow of a soft tissue tumor (Fig. 25-4). CT scan shows characteristic fatty tumor with an occasional phlebolith. They are said to have a “honeycomb” appearance. On MRI the fat portion will have high signal intensity on T1-weighted images, and the vascular portion will be high intensity on T2-weighted images (Fig. 25-5).

Resection is necessary for enlargement, pain, or if the diagnosis is in doubt. Occasionally the mass will be large enough to cause congestive heart failure, but this is extremely rare. Extension of the mass into the spinal canal should be checked, for this will greatly complicate the resection. Preoperative embolization has been used for large tumors to decrease intraoperative blood loss but is not necessary for smaller lesions and is not curative alone. Resection with negative margins is curative.

FIGURE 25-4 ■ Rib radiograph showing a mass (arrow) that is located on the seventh rib and expands beyond the irregular cortex. Calcification inside the mass presents a so-called honeycomb appearance. (Reprinted with permission from Okumura T, et al: Hemangioma of the rib: a case report. *Jpn J Clin Oncol* 30:354–357, 2000.)

FIGURE 25-5 ■ MRI showing the coronal plan of T1 image demonstrating lobulated masses in the chest wall. The involvement of the supra- and subclavicular region, severe deformity of the chest, and thoracic scoliosis are clearly evident. (Reprinted with permission from Margaritora S, et al: Giant neurofibroma of the chest wall. *Eur J Cardiothorac Surg* 21:339, 2002.)

Neurofibroma/Neurolemmoma

These are tumors that arise from nerve cells (neurofibroma) or nerve sheath cells (neurolemmoma or schwannoma) that are in the chest wall. Neurofibromas can be associated with neurofibromatosis type I, a disorder caused by the mutation of a gene on chromosome 17 that codes for neurofibromin, a negative regulator of the Ras oncogene signal transduction pathway.³⁴ These tumors present either as singular painless enlargements in the isolated form or numerous tumors on the chest wall and in other areas. They can cause electric shock-like symptoms. Radiographically they are smooth bordered masses that enhance with gadolinium with MRI.³⁵ The neurofibromas can enlarge markedly, indicating they have undergone malignant transformation. The tumors should be removed for symptom control and if malignant transformation is suspected.

Desmoid Tumors

These tumors, although classified as benign because they do not metastasize, are locally aggressive low-grade sarcomas that arise from fascia and connective tissue. Approximately 20% develop in the chest wall. The cause is unknown, but they are associated with trauma, familial adenomatous polyposis, and Gardner syndrome. Some of the tumors are positive for estrogen and/or progesterone receptors, implying that hormonal therapy with agents like tamoxifen may be helpful. Radiographically they tend to be homogenous masses with indistinct borders. Surgical resection with wide margins is the treatment of choice. This may be difficult with tumors that involve the axilla, clavicular area, or the brachial plexus.

Abbas's series from the Mayo Clinic studied 53 patients (24 men and 29 women) whose median age was 39 years old.³⁶ A palpable mass was present in 66%, pain was present in 42%, and no signs or symptoms were present in 10% of the patients. All the patients had wide radical excision attempted, and it was completed in 44. Seven had microscopic margins and two (R1 resection) had grossly positive margins (R2 resection). Follow-up was complete in 51 patients for a median of 53 months. The 5-year survival was 93%; however, 30% had a local recurrence. Radiation therapy was used in some of the recurrent tumors, but whether or not it was useful to prevent further recurrence is unknown. These patients should be followed for life because some of the recurrences occurred long after the initial resection.³⁷

Malignant Lesions

Chondrosarcoma

Chondrosarcomas are the most common malignant primary chest wall tumor in adults. They arise de novo or from degeneration of a chondroma, exostosis, or osteochondroma. They may have a relationship to remote trauma. In large series, approximately 80% occur in the ribs and 20% occur in the sternum.^{20,38} Presentation is typically a hard, slowly enlarging painful mass. On radiographic imaging it is a poorly defined lobulated mass,

FIGURE 25-6 ■ Large left anterior chest wall chondrosarcoma.

often with cortical destruction and varying amounts of calcification (Fig. 25-6). Metastatic lesions are seen in roughly 10% of patients, with higher-grade tumors more often presenting with metastases.

Definitive diagnosis is made by pathologic examination, which shows chondroid matrix with increased cellularity, binucleate cells, and increased mitotic activity.³¹ Therapy is wide surgical excision when possible; radiation and chemotherapy have little to offer these patients.

In a large series from Scandinavia, 106 patients treated over a 22-year (1980-2002) period were analyzed.³⁸ The average age was 59 years old and there were 59 men and 47 women. All patients were treated with surgical excision, except for 9 who were deemed too ill to undergo resection. The overall 10-year survival was 64% and was improved for those that could undergo wide excision.

In another series from the Mayo clinic that examined 96 patients with chondrosarcoma of the chest wall, researchers found a similar age at presentation (median age 53.5) and a similar distribution of gender (55 men, 41 women).²⁰ Seventy-two of the patients had their initial resection at Mayo clinic, 28 underwent wide excision (2 to 4 cm margin), 25 had local excision (<2-cm margin), and 19 underwent palliative resection. The long-term survival was dependent on the extent of resection; those that had wide excision had a 96.4% 10-year survival, those with a local resection had a 65.4% 10-year survival, and those with a palliative resection only had a 14% 10-year survival (Fig. 25-7).

Patients that present with a chondrosarcoma should undergo wide excision (at least 4-cm margins) if possible. Radiation therapy is usually given to patients who cannot undergo a wide excision because the tumor is too close to vital structures. Follow-up should last for the rest of the patients' lives, because these tumors have been known to recur late after surgical resection.

FIGURE 25-7 ■ Survival rate of resected chondrosarcoma according to margin of resection. (From McAfee MK, et al: Chondrosarcoma of the chest wall: factors affecting survival. *Ann Thorac Surg* 40:535–541, 1985.)

FIGURE 25-8 ■ Computed tomography scan of an osteosarcoma of the left chest wall.

Osteosarcoma

Osteosarcoma are the most common bone tumor overall, but less common than chondrosarcoma in the chest wall. They occur in younger patients (10 to 25 years old) and can occur later in life in association with Paget disease, prior radiation therapy (with at least a 10-year latency period), or in old bone infarcts.³⁹ There is a higher risk in patients with retinoblastoma (*RB1* mutation on chromosome 13q14) and in Li-Fraumeni syndrome (*p53* mutation). The tumor presents as a rapidly expanding painful mass. Elevations in alkaline phosphatase can be seen, but this is a nonspecific finding. On radiograph a classic sunburst pattern is sometimes seen. Osteosarcomas are typically more calcified than chondrosarcomas (Fig. 25-8). Codman triangle refers to the shape formed by the elevated periosteum and the cortex seen in some tumors. A CT of the chest is an important study, because

at least 20% of patients will present with pulmonary metastases.

Treatment is neoadjuvant chemotherapy (doxorubicin, methotrexate, and cisplatin and wide local excision.⁴⁰ Radiation therapy is ineffective. The 5-year survival ranges from 14% to 50% and is related to response rate to chemotherapy and the ability to undergo wide excision. Pulmonary metastasectomy can prolong life, so patients should be followed carefully.

Ewing Sarcoma (Small Round Cell)

Ewing sarcoma, along with Askin tumors and primitive neuroectodermal tumors (PNETs), make up a group of small round cell tumors that have a neural origin.⁴¹ Most of these tumors have a translocation mutation between the long arms of chromosomes 11 and 22 [t(11:22)(q24;q12)].⁴² This is the most common tumor in pediatric and young adult patients, and approximately 6% occur in the rib. Only 15% of Ewing sarcomas occur on the chest wall, whereas 50% of PNETs are found here.

Ewing sarcomas present as a painful mass, often accompanied by fever, malaise, and weight loss. The erythrocyte sedimentation rate (ESR) may be elevated. Radiologically they are large uncalcified tumors with soft tissue and bone destruction. An onion peel or sunburst pattern can be seen on CT. Pathology shows small round blue cells with scant clear cytoplasm, which stain positive with periodic acid–Schiff because of the presence of glycogen.³¹ PNETs have rosettes, dark oval nuclei with neurofibrillary cores that allow them to be differentiated from Ewing tumors.

Treatment of Ewing tumor is with neoadjuvant chemotherapy followed by wide resection if possible. Because this tumor may spread within the marrow of the rib, consideration should be given to removal of the entire rib during the resection. Survival rates depend on the response to chemotherapy and the ability to perform a wide complete resection.

Plasmacytoma

Plasmacytoma of the chest wall is a growth of monoclonal plasma cells in the rib that, unlike multiple myeloma, is a solitary lesion. It usually appears in elderly men as a pain in the rib without a palpable mass. Radiographically it appears as an osteolytic process with paracostal opacities frequently present. A core biopsy is performed to make the diagnosis, and then the lesion is treated with radiation therapy. A dose of 5000 to 6000 cGy is recommended.¹⁶ If disseminated multiple myeloma does not develop, the cure rate is quite good. Unfortunately approximately two thirds of patients progress to systemic disease within 3 years.³¹

Other Sarcomas

Almost any other type of sarcoma can occur primarily in the chest wall, although they are quite rare. More frequent types include undifferentiated pleomorphic sarcoma (formerly known as malignant fibrous histiocytoma [MFH]), liposarcoma, neurofibrosarcoma,

rhabdomyosarcoma, and radiation-induced sarcomas. All have a common presentation as a painful mass that is enlarging. The treatment, in general, is wide excision with or without additional radiation and/or chemotherapy.⁴³ Long-term survival depends on grade of tumor and the ability to perform wide excision.

SUMMARY

Primary chest wall tumors comprise a wide variety of cell types with often confusing presentations. Establishment of an accurate pathologic diagnosis without interfering with subsequent treatment options is an important principle. For most tumors, wide excision is the key to therapy and should be performed at a center where physicians have experience treating these unusual lesions.

SUMMARY

Thoracic outlet syndrome, a term coined by Rob and Standover,¹ refers to compression of the subclavian vessels and brachial plexus at the superior aperture of the chest. It was previously designated, according to presumed etiologies, as *scalenus anticus*, *costoclavicular*, *hyperabduction*, *cervical rib*, and *first thoracic rib syndromes*. The various syndromes are similar, and the compression mechanism is often difficult to identify. Most compressive factors operate against the first rib (Fig. 26-1).^{2,3}

The various symptoms and presentations of thoracic outlet syndrome (TOS) are related to which structure or

structures are affected, the subclavian vein, subclavian artery or brachial plexus.⁴⁻⁶

Neurovascular compression can occur between the anterior and middle scalene muscles while passing over the first rib, in the space between the clavicle and first rib, or in the subcoracoid tunnel at the insertion of the pectoralis minor muscle.⁷⁻¹¹

HISTORICAL ASPECTS

Until 1927, the cervical rib was commonly thought to be the cause of symptoms of this syndrome. Galen and Vesalius first described the presence of a cervical rib.¹² Hunauld, who published an article in 1742, is credited by

[†]Deceased.

FIGURE 26-1 ■ Diagram of the relationships of muscle, ligament, and bone abnormalities in the thoracic outlet that can compress neurovascular structures against the first rib.

Keen¹³ as being the first to describe the importance of the cervical rib in causing symptoms. In 1818, Cooper treated symptoms of cervical rib with some success,¹⁴ and in 1861, Coote¹⁵ performed the first cervical rib removal. Halsted¹⁶ stimulated interest in dilation of the subclavian artery distal to cervical ribs, and Law¹⁷ reported the role of adventitious ligaments in the cervical rib syndrome. In 1927, Adson and Coffey¹⁴ suggested the role of the scalenus anticus muscle in cervical rib syndrome. Naffziger and Grant¹⁸ and Ochsner and associates¹⁹ popularized sectioning of the scalenus anticus muscle. Falconer and Weddell²⁰ and Brintnall and colleagues²¹ incriminated the costoclavicular membrane in the production of neurovascular compression. In 1945, Wright²² described the hyperabduction syndrome with compression in the costoclavicular area by the tendon of the pectoralis minor. Rosati and Lord²³ added claviclectomy to anterior exploration, scalenotomy, cervical rib resection (when one was present), and sectioning of the pectoralis minor and subclavian muscles and of the costoclavicular membrane. The role of the first rib in causing symptoms of neurovascular compression was recognized by Bramwell²⁴ in 1903. Murphy²⁵ is credited with the initial resection of the first rib in 1910. He used a supraclavicular approach to the resection, whereas the primary surgical approach for decades had been a supraclavicular scalenotomy, without rib resection.²⁶

Brickner,²⁷ Brickner and Milch,²⁸ and Telford and coworkers^{29,30} suggested that the first rib was the culprit. Clagett² emphasized the first rib and its resection through the posterior thoracoplasty approach to relieve neurovascular compression. In 1962, Falconer and Li³¹ reported the anterior approach for first rib resection, whereas

Roos³² in 1966 introduced the transaxillary route for first rib resection and extirpation. Caldwell and colleagues³³ introduced the method of measuring motor conduction velocities across the thoracic outlet in diagnosing TOS. Urschel and Razzuk³⁴ popularized reoperation for recurrent TOS.

Regardless of the mode of presentation, the optimal diagnosis and treatment of TOS remains elusive, and treatments have therefore varied.^{35,36,37}

SURGICAL ANATOMY

At the superior aperture of the thorax, the subclavian vessels and the brachial plexus traverse the cervicoaxillary canal to reach the upper extremity. The cervicoaxillary canal is divided by the first rib into two sections: the proximal one, composed of the scalene triangle and the costoclavicular space, and the distal one, composed of the axilla. The proximal division is the more critical for neurovascular compression. It is bounded superiorly by the clavicle, inferiorly by the first rib, anteromedially by the costoclavicular ligament, and posterolaterally by the scalenus medius muscle and the long thoracic nerve. The scalenus anticus muscle, which inserts on the scalene tubercle of the first rib, divides the costoclavicular space into two compartments: the anteromedial one containing the subclavian vein and the posterolateral one containing the subclavian artery and the brachial plexus (Fig. 26-2). The latter compartment, which is bounded by the scalenus anticus anteriorly, the scalenus medius posteriorly, and the first rib inferiorly, is called the *scalene triangle*.

FIGURE 26-2 ■ Anatomic dissection from the transaxillary approach, showing the relationship of the neurovascular bundle, the scalenus anterior muscle, and the long thoracic nerve along the posterior border of the scalenus medius muscle.

FUNCTIONAL ANATOMY

The cervicoaxillary canal, particularly its proximal segment (the costoclavicular area), normally has ample space for passage of the neurovascular bundle without compression. Narrowing of this space occurs during functional maneuvers. It narrows during abduction of the arm because the clavicle rotates backward toward the first rib and the insertion of the scalenus anticus muscle. In hyperabduction, the neurovascular bundle is pulled around the pectoralis minor tendon, the coracoid process, and the head of the humerus. During this maneuver, the coracoid process tilts downward and thus exaggerates the tension on the bundle. The sternoclavicular joint, which ordinarily forms an angle of 15 to 20 degrees, forms a smaller angle when the outer end of the clavicle descends (as in drooping of the shoulders in poor posture), and narrowing of the costoclavicular space may occur.¹⁵ Normally during inspiration, the scalenus anticus muscle raises the first rib and thus narrows the costoclavicular space. This muscle can cause an abnormal lift of the first rib, as in cases of severe emphysema or excessive muscular development, which is seen in young adults.

The scalene triangle, which normally occurs between the scalenus anticus anteriorly, the scalenus medius posteriorly, and the first rib inferiorly, permits the passage of the subclavian artery and the brachial plexus, which are in direct contact with the first rib. The space of the triangle is 1.2 cm at its base and approximately 6.7 cm in height (Fig. 26-3). There is a close-fitting relationship between the neurovascular bundle and this triangular space. Anatomic variations can narrow the superior angle of the triangle, cause impingement on the upper components of the brachial plexus, and produce the upper type of scalenus anticus syndrome that involves the trunk containing elements of C5 and C6. If the base of the triangle is raised, compression of the subclavian artery and the trunk containing components of C7, C8, and T1 results in the lower type of scalenus anticus syndrome. Both types have been described by Swank and Simeone.³⁸

FIGURE 26-3 ■ The scalene (anterior) triangle, with its measurements and the narrow interval through which the neurovascular bundle passes. (From Rosati LM, Lord JV: *Neurovascular compression syndromes of the shoulder girdle*, New York, 1961, Grune & Stratton.)

COMPRESSION FACTORS

Many factors may cause compression of the neurovascular bundle at the thoracic outlet, but the basic factor is deranged anatomy, to which congenital, traumatic, and, occasionally, atherosclerotic factors may contribute (Box 26-1).²³ Bony abnormalities are present in approximately 30% of patients as cervical rib, bifid first rib, and fusion of first and second ribs; clavicular deformities; or previous thoracoplasties.³ These abnormalities can be visualized on the plain posteroanterior chest film, but special radiographic views of the lower cervical spine may be required in some cases of cervical ribs.

SYMPTOMS AND SIGNS

The symptoms of TOS depend on whether the nerves or blood vessels, or both, are compressed in the cervicoaxillary canal. Neurogenic manifestations are observed more frequently than vascular ones. Symptoms consist of pain and paresthesias, which are present in approximately 95% of cases, and motor weakness and occasionally atrophy of hypothenar and interosseous muscles, which is the ulnar type of atrophy, in approximately 10%. The symptoms occur most commonly in areas supplied by the ulnar nerve, which include the medial aspects of the arm and hand, the fifth finger, and the lateral aspects of the fourth finger. The onset of pain is usually insidious and commonly involves the neck, shoulder, arm, and hand. The pain and paresthesias may be precipitated by

TRAUMATIC

- Fracture of clavicle
- Dislocation of head of humerus
- Crushing injury to upper thorax
- Sudden, unaccustomed muscular efforts involving shoulder girdle muscles
- Cervical spondylosis and injuries to cervical spine

ATHEROSCLEROSIS

strenuous physical exercise or sustained physical effort with the arm in abduction and the neck in hyperextension. Symptoms may be initiated by sleeping with the arms abducted and the hands clasped behind the neck. In other cases, trauma to the upper extremities or the cervical spine is a precipitating factor. Physical examination may be noncontributory. When present, objective physical findings usually consist of hypesthesia along the medial aspects of the forearm and hand. Atrophy, when evident, is usually described in the hypothenar and interosseous muscles with clawing of the fourth and fifth fingers. In the upper type of TOS, in which components of C5 and C6 are involved in compression, pain is usually in the deltoid area and the lateral aspects of the arm. The presence of this pain should induce action to exclude a herniated cervical disc.²³ Entrapment of C7 and C8 components that contribute to the median nerve produces symptoms in the index finger and sometimes the middle finger. Components of C5, C6, C7, C8, and T1 can occur at the thoracic outlet by a cervical rib and produce symptoms of various degrees in the distribution of these nerves (Fig. 26-4).

In some patients, the pain is atypical, involving the anterior chest wall or parascapular area, and is termed *pseudoangina* because it simulates angina pectoris. These patients may have normal coronary arteriograms and ulnar nerve conduction velocities decreased to values of

48 m/sec and less, which strongly suggests the diagnosis of TOS. The shoulder, arm, and hand symptoms that usually provide the clue for the diagnosis of TOS may initially be absent or minimal compared with the severity of the chest pain. The diagnosis of TOS is frequently overlooked; many of these patients are committed to becoming “cardiac cripples” without an appropriate diagnosis, or they develop severe psychological depression when told that their coronary arteries are normal and that they have no significant cause for their pain.³⁹

Symptoms of arterial compression include coldness, weakness, easy fatigability of the arm and hand, and pain that is usually diffuse.^{40,41} Raynaud phenomenon is noted in approximately 7.5% of patients with TOS.⁴⁰ Unlike Raynaud disease, which is usually bilateral and symmetrical and elicited by cold or emotion, Raynaud phenomenon in neurovascular compression is usually unilateral and is more likely to be precipitated by hyperabduction of the involved arm, turning of the head, or carrying of heavy objects. Sensitivity to cold may also be present. Symptoms include sudden onset of cold and blanching of one or more fingers, followed slowly by cyanosis and persistent rubor. Vascular symptoms in neurovascular compression may be precursors of permanent arterial thrombosis.²³ Arterial occlusion, usually of the subclavian artery, when present, is manifested by persistent coldness, cyanosis or pallor of the fingers, and in some instances, ulceration or gangrene. Palpation in the parascapular area may reveal prominent pulsation, which indicates poststenotic dilation or aneurysm of the subclavian artery (Fig. 26-5).⁴²

Less frequently, the symptoms are those of venous obstruction or occlusion, commonly recognized as effort thrombosis, or Paget-Schroetter syndrome. The condition characteristically results in edema, discoloration of the arm, distention of the superficial veins of the limb and shoulder, and some degree of aches and pains. In some patients, the condition is observed on waking; in others, it follows sustained efforts with the arm in abduction. Sudden backward and downward bracing of the shoulders or heavy lifting or strenuous physical activity involving the arm may constrict the vein and initiate venospasm, with or without subsequent thrombosis. On examination, in cases of definite venous thrombosis, there is usually moderate tenderness over the axillary vein, and a cordlike structure may be felt that corresponds to the course of the vein. The acute symptoms may subside in a few weeks or days as the collateral circulation develops. Recurrence follows with inadequacy of the collateral circulation.⁴³

Objective physical findings are more common in patients with primarily vascular rather than neural compression. Loss or diminution of radial pulse and reproduction of symptoms can be elicited by the three classic clinical maneuvers: the Adson or scalene test,⁴⁴ the costoclavicular test, and the hyperabduction test.⁴⁵

DIAGNOSIS

The diagnosis of TOS includes history, physical and neurologic examinations, radiography of the chest and cervical spine, electromyography, and ulnar nerve conduction

FIGURE 26-4 ■ Compression caused by congenital rib abnormalities. (Reprinted from www.netterimages.com. © Elsevier, Inc. All rights reserved.)

velocity (UNCV). In some cases with atypical manifestations, other diagnostic procedures such as cervical myelography, periphery⁴² or coronary arteriography, or phlebography⁴⁶ should be considered. A detailed history and physical and neurologic examinations can often result in a tentative diagnosis of neurovascular compression. This diagnosis is strengthened when one or more of the classic clinical maneuvers is positive and is confirmed by the finding of decreased UNCV.⁴⁷

Clinical Maneuvers

The clinical evaluation is best based on the physical findings of loss or decrease of radial pulses and reproduction of symptoms that can be elicited by the following three classic maneuvers.^{23,45}

The Adson or scalene test (Fig. 26-6)⁴⁴ tightens the anterior and middle scalene muscles and thus decreases

the interspace and magnifies any preexisting compression of the subclavian artery and brachial plexus. The patient is instructed to take and hold a deep breath, extend the neck fully, and turn the head toward the side. Obliteration or decrease of the radial pulse suggests compression.

For the costoclavicular test (military position; Fig. 26-7), the shoulders are drawn downward and backward. This maneuver narrows the costoclavicular space by approximating the clavicle to the first rib and thus tends to compress the neurovascular bundle. Changes in the radial pulse with production of symptoms indicate compression.

For the hyperabduction test (Fig. 26-8), the arm is hyperabducted to 180 degrees, resulting in the components of the neurovascular bundle being pulled around the pectoralis minor tendon, the coracoid process, and the head of the humerus. A decrease in the radial pulse suggests compression.

Radiographic Findings

Films of the chest and cervical spine are helpful in revealing bony abnormalities, particularly cervical ribs (Fig. 26-9) and bony degenerative changes. If osteophytic changes and intervertebral space narrowing are present on plain cervical films, a cervical computed tomographic scan should be obtained to rule out bony encroachment and narrowing of the spinal canal and the intervertebral foramina.

FIGURE 26-5 ■ Arteriogram showing poststenotic dilation (arrow) of the right subclavian artery secondary to thoracic outlet compression.

Nerve Conduction Velocity and Electromyography

This test is widely used in differential diagnosis of the causes of arm pain, tingling, and numbness with or without motor weakness of the hand. Such symptoms can result from compression at various sites: in the spine; at the thoracic outlet; around the elbow, where it causes tardy ulnar nerve palsy; or on the flexor aspects of the wrist, where it produces carpal tunnel syndrome. For diagnosis and localization of the site of compression, cathodal stimulation is applied at various points along the course of the nerve. Motor conduction velocities of the ulnar, median, radial, and musculocutaneous nerves can be measured reliably.⁴⁸ Caldwell and colleagues³³ have improved the technique of measuring UNCV for evaluation of patients with thoracic outlet compression. Conduction velocities over proximal and distal segments of the ulnar nerve are determined by recording the action potentials generated in the hypothenar or first dorsal interosseous muscles. The points of stimulation are the supraclavicular fossa, middle upper arm, below the elbow, and at the wrist (Fig. 26-10).⁴¹

Method of Measuring Conduction Velocities

Equipment

Electromyographic examination of each upper extremity and determination of the conduction velocities are done with the Meditron 201 AD or 312 or the TECA-3 electromyograph. Coaxial cable with three needles or surface electrodes is used to record muscle potentials, which appear on the fluorescent screen (Fig. 26-11).

FIGURE 26-9 ■ Radiographic film showing bilateral cervical ribs (arrows).

FIGURE 26-11 ■ TECA-3 electromyograph using a coaxial cable and three needles to record generated action potentials.

FIGURE 26-10 ■ The four ulnar nerve stimulation points: in the supraclavicular fossa (Erb point over the trunks of the plexus), above the elbow, below the elbow, and at the wrist.

Technique

The conduction velocity is determined with the Krusen-Caldwell technique.³³ The patient is placed on the examination table with the arm fully extended at the elbow and in approximately 20 degrees of abduction at the shoulder

FIGURE 26-12 ■ A stimulating electrode positioned over the cords of the brachial plexus at Erb point in the supraclavicular fossa posterior to the sternocleidomastoid muscle, which is the stimulation site of the brachial plexus across the outlet.

to facilitate stimulation over the course of the ulnar nerve. The ulnar nerve is stimulated at the four points by a special stimulation unit (Fig. 26-12) that imparts an electrical stimulus with strength of 350 V with the patient's load, which is approximately equal to 300 V with the patient's load with a skin resistance of 5000 Ω . Supramaximal stimulation is used at all points to obtain maximal response. The duration of the stimulation is 0.2 msec, except for muscular individuals, for whom it is 0.5 msec. Time of stimulation, conduction delay, and muscle response appear on the TECA screen; time markers occur each millisecond on the sweep.

The latency period to stimulation from the four points of stimulation to the recording electrode is obtained from the TECA digital recorder or calculated from the tracing on the screen.

Calculation of Velocities

After the latencies, which are expressed in milliseconds, are obtained, the distance in millimeters between two

FIGURE 26-13 ■ The sites of stimulation and the formula for calculating ulnar nerve conduction velocity (UNCV).

adjacent sites of stimulation is measured with steel tape. The velocities, which are expressed in meters per second, are calculated by subtracting the distal latency from the proximal latency and dividing the distance between two points of stimulation by the latency difference (Fig. 26-13) according to the following formula:

velocity (m/sec) = distance between adjacent stimulation points (mm) ÷ difference in latency between adjacent stimulation points (msec)

Normal Ulnar Nerve Conduction Velocities

The normal values of the UNCVs according to the Krusen-Caldwell technique³³ are 72 m/sec or greater across the outlet, 55 m/sec or greater around the elbow, and 59 m/sec or greater in the forearm. Wrist delay is 2.5 to 3.5 msec. Decreased velocity in a segment or increased delay at the wrist indicates compression, injury, neuropathy, or neurologic disorders. Decreased velocity across the outlet is consistent with TOS. Decreased velocity around the elbow signifies ulnar nerve entrapment or neuropathy. Increased delay at the wrist is encountered in carpal tunnel syndrome.

Grading of Compression

The clinical picture of TOS correlates fairly well with the conduction velocity across the outlet. Any value less than 70 m/sec indicates neurovascular compression. The severity is graded according to decrease of velocity across the thoracic outlet: compression is called *slight* when the velocity is 66 to 69 m/sec, *mild* when the velocity is 60 to 65 m/sec, *moderate* when the velocity is 55 to 59 m/sec, and *severe* when the velocity is 54 m/sec or less.

Angiography

Simple clinical observations usually suffice to determine the degree of vascular impairment in the upper extremity. Peripheral angiography^{42,49} is indicated in some cases, as in the presence of a paraclavicular pulsating mass, the absence of radial pulse, or the presence of supraclavicular or infraclavicular bruits. Retrograde or antegrade arteriograms of the subclavian and brachial arteries should be obtained to demonstrate or localize the pathology. In cases of venous stenosis or obstruction, as in Paget-Schroetter syndrome, phlebography is used to determine the extent of thrombosis and the status of the collateral circulation (Fig. 26-14).

Magnetic resonance imaging in association with postural maneuvers is gaining popularity in the workup and diagnosis of TOS. Magnetic resonance imaging allows for better visualization and identification of the different compartments of the cervicothoracic-brachial junction as well as demonstration of any compression of the neural or vascular structures involved.⁵⁰⁻⁵²

The study involves imaging of the involved shoulder with the patient's affected arm at the side and over the head to determine the impact of the first rib on the vessels and nerves.

DIFFERENTIAL DIAGNOSIS

TOS should be differentiated from various neurologic, vascular, cardiac, pulmonary, and esophageal conditions (Box 26-2).^{3,23,47,53}

Neurologic causes of pain in the shoulder and arm are more difficult to recognize and may arise from involvement of the nervous system in the spine, the brachial plexus, or the peripheral nerves. A common neurologic

FIGURE 26-14 ■ Phlebogram showing total occlusion (arrow) with minimal collateral circulation of the left subclavian vein resulting from thoracic outlet compression. At operation, no thrombus was present in the vein, and obstruction was relieved by removing the first rib.

BOX 26-2 Differential Diagnoses of Thoracic Outlet Syndrome Nerve Compression

CERVICAL SPINE

- Ruptured intervertebral disc
- Degenerative disease
- Osteoarthritis

TUMORS

- Spinal cord tumors
- Brachial plexus superior pulmonary sulcus tumors

PERIPHERAL NERVE

- Postural palsy
- Peripheral nerves entrapment neuropathy
- Carpal tunnel—median nerve
- Ulnar nerve—elbow
- Radial nerve
- Suprascapular nerve
- Medical neuropathies

VASCULAR PHENOMENA

- Arterial arteriosclerosis-aneurysm occlusive
- Thromboangiitis obliterans
- Embolism
- Vasculitis, collagen disease, panniculitis
- Venous thrombophlebitis
- Mediastinal venous obstruction
- Raynaud disease
- Reflex vasomotor dystrophy
- Causalgia

OTHER DISEASES

- Angina pectoris
- Esophageal spasm

cause of pain in the upper extremities is a herniated cervical intervertebral disc. The herniation almost invariably occurs at the interspace between the fifth and the sixth or the sixth and the seventh cervical vertebrae and produces characteristic symptoms. Onset of pain and stiffness of the neck is manifested with varying frequency. The pain radiates along the medial border of the scapula into the shoulder, occasionally into the anterior chest wall, and down the lateral aspect of the arm, at times into the fingers. Numbness and paresthesias in the fingers may be present. The segmental distribution of pain is a prominent feature. A herniated disc between the C5 and the C6 vertebrae, which compresses the C6 nerve root, causes pain or numbness primarily in the thumb and to a lesser extent in the index finger. The biceps muscle and the radial wrist extensor are weak, and the reflex of the biceps muscle is reduced or abolished. A herniated disc between the C6 and the C7 vertebrae, which compresses the C7 nerve root, produces pain or numbness in the index finger and weakness of index finger flexion and ulnar wrist extension; the triceps muscle is weak and its reflex is reduced or abolished. Any of these herniated discs can cause numbness along the ulnar border of the arm and hand because of spasm of the scalenus anticus muscle. Rarely, pain and paresthesias in the ulnar distribution may be related to herniation between the C7 and the T1 vertebrae, which causes compression of the C8 nerve root. Compression of the latter nerve root produces weakness of intrinsic hand muscles.^{23,54} Although rupture of the fifth and sixth discs produces hypesthesia in this area, only rupture of the seventh disc produces pain down the medial aspect of the arm.²³

The diagnosis of a ruptured cervical disc is based primarily on the history and physical findings; lateral radiography of the cervical spine reveals a loss or reversal of cervical curvature, with the apex of the reversal of curvature at the level of the disc being involved. Electromyography can localize the site and extent of the nerve root irritation. When a herniated disc is suggested, cervical myelography should be used to confirm the diagnosis.^{23,54}

Another condition that causes upper extremity pain is cervical spondylosis, a degenerative disease of the intervertebral disc and the adjacent vertebral margin that causes spur formation and the production of ridges into the spinal canal or intervertebral foramina. Radiographic films and a computed tomographic scan of the cervical spine and electromyography help in making the diagnosis of this condition (Fig. 26-15).

Several arterial and venous conditions can be confused with TOS (see Box 26-2). The differentiation can often be made clinically.²³

In atypical patients with chest pain alone, it is important to consider TOS in addition to angina pectoris. Exercise stress testing and coronary angiography may exclude coronary artery disease when there is a high index of suspicion of angina pectoris.^{39,45}

THERAPY

Patients with neurogenic TOS should be given physiotherapy when the diagnosis is made. Proper physiotherapy

FIGURE 26-15 ■ Computed tomographic scan showing osteophytic ingrowth (arrow) in the spinal canal (A) and narrowing of the anteroposterior diameter of the spinal canal (B; double-headed arrow) in a patient with the typical clinical picture of thoracic outlet syndrome.

includes heat massages, active neck exercises, stretching of the scalenus muscles, strengthening of the upper trapezius muscle, and posture instruction. Because sagging of the shoulder girdle, which is common among middle-aged people, is a major cause in this syndrome, many patients with less severe cases are improved by strengthening the shoulder girdle and by improving posture.⁵⁴

Most patients with TOS who have UNCVs of more than 60 m/sec improve with conservative management. If the conduction velocity is below that level, most patients, despite physiotherapy, may remain symptomatic, and surgical resection of the first rib and correction of other bony abnormalities may be needed to provide relief of symptoms.^{40,41,55}

If symptoms of neurovascular compression continue after physiotherapy, and the conduction velocity shows slight or no improvement or regression, surgical resection of the first rib and cervical rib, when present, should be considered.^{40,41,55} Clagett² popularized the high posterior thoracoplasty approach for first rib resection, Falconer and Li³¹ emphasized the anterior approach, and Roos³² introduced the transaxillary route in 1966.

The transaxillary route is an expedient approach for complete removal of the first rib with decompression of the seventh and eighth cervical and first thoracic nerve roots and the lower trunks of the brachial plexus. First rib resection can be performed without the need for major muscle division, as in the posterior approach²; the need for retraction of the brachial plexus, as in the anterior supraclavicular approach³¹; and the difficulty of removing the posterior segment of the rib, as in the infraclavicular approach. In addition, first rib resection shortens the postoperative disability and provides better

cosmetic results than the anterior and posterior approaches do, particularly because 80% of patients are female.^{40,41,47,56}

Technique of Transaxillary Resection of the First Rib

The patient is placed in the lateral position with the involved extremity abducted to 90 degrees by traction straps wrapped around the forearm and attached to an overhead pulley. An appropriate weight, usually 2 lb (907 g), is used to maintain this position without undue traction (Fig. 26-16).^{3,45} Two arm holders are used to hold the arm at 90 degrees from the body and to prevent further hyperabduction.

A 3- to 4-inch transverse incision is made in the axilla below the hairline between the pectoralis major and the latissimus dorsi muscles and is then deepened to the external thoracic fascia (Fig. 26-17). Care should be taken to prevent injury to the intercostobrachial cutaneous nerve, which passes from the chest wall to the subcutaneous tissue in the center of the operative field. The use of electrocautery in that area should be minimized.

The dissection is extended cephalad along the external thoracic fascia up to the first rib. With gentle dissection, the neurovascular bundle and its relationship to the first rib and both scalenus muscles are clearly outlined, which helps to avoid injury to its components (Fig. 26-18). The insertion of the scalenus anticus muscle is identified, skeletonized, and divided (Fig. 26-19). The first rib is dissected subperiosteally with a periosteal elevator and is separated carefully from the underlying pleura to avoid pneumothorax. A segment of the middle portion of the rib is

FIGURE 26-16 ■ The arm is abducted to 90 degrees by traction straps on the forearm and is attached to an overhead pulley.

FIGURE 26-17 ■ A transverse incision is made in the axilla below the hairline between the pectoralis major and the latissimus dorsi muscles and is extended to the chest wall.

FIGURE 26-18 ■ Schematic drawing showing the relationship of the neurovascular bundle to the scalene muscles, first rib, costoclavicular ligament, and subclavius muscle.

FIGURE 26-19 ■ Schematic drawing showing division of the insertion of the scalenus anterior muscle on the first rib and removal of a segment of the midportion of the first rib.

resected, followed by subperiosteal dissection and resection of the anterior portion of the rib at the costochondral junction. After the costoclavicular ligament is cut, the posterior segment of the rib is similarly dissected subperiosteally and resected in fragments, including the articulation with the transverse process, the neck, and the head. The scalenus medius muscle should not be cut from its insertion on the second rib, but rather stripped with a periosteal elevator to avoid injury to the long thoracic nerve that lies on its posterior margin. The neck and head of the first rib are removed completely with a long, special Urschel double-action pituitary and Urschel Lexel rongeurs. The eighth cervical and first thoracic nerve roots can be visualized at this point. If a cervical rib is present, its anterior portion, which usually articulates with the first rib, should be resected when the middle portion of the first rib is removed. The remaining segment of the cervical rib should be removed after removal of the posterior segments of the first rib. The wound is drained,

and only the subcutaneous tissues and skin require closure, because no large muscles have been divided. The patient is encouraged to use the arm for self-care, but to avoid heavy lifting until at least 3 months after operation. Cervical muscle stretching should be started at the end of the first week, and gentle exercising of the arm can be started at the end of the third week after operation.

It is preferable to remove the first rib entirely, including the head and neck, to avoid future irritation of the plexus, because a residual portion, particularly if long, will cause recurrence of symptoms.

Technique of Using Video-Assisted Thoracic Surgery for Transaxillary Resection of the First Rib

A more recent option for the transaxillary resection of the first rib is a video-assisted thoracic surgery (VATS) approach for TOS.

After the administration of single-lung, general anesthesia with a double lumen endotracheal tube, the patient is placed in the lateral decubitus position with the arm resting on pillows for support or on an airplane arm support. VATS is performed with a 5-mm, 30-degree thoracoscope introduced through the fifth intercostal space at the midaxillary line. Optimal exposure for the first rib is achieved with reverse Trendelenburg and CO₂ insufflation to an intrathoracic pressure of 6 to 10 mm Hg. A 3-cm incision is made at the bottom of the hair line in the midaxillary line between the pectoralis and latissimus dorsi muscles (Fig. 26-20). Care is taken to minimize the use of electrocautery near the intercostobrachial cutaneous nerve.

Through the axillary incision, blunt dissection is performed on the surface of the chest wall superiorly to the first rib. The first rib is identified by its characteristic flat, broad surface, which is different from the other ribs and

visualization of the subclavian artery in the cupola. A periosteal elevator is then used to dissect the lateral surface of the rib. To protect the neurovascular bundle, the surgeon's index finger is kept between the brachial plexus and the area of the rib being dissected. The dissection is sequentially carried out on the lateral, inferior, and the pleural surfaces of the rib. At that point, the pleura near the second rib is opened to see the surface of the dissected rib. By opening the pleura near the second rib, the intercostal muscle that hangs in to the pleural space obstructs the view of the first rib less than if the pleura is entered near the first rib (Figs. 26-21 and 26-22).

The first rib can now be seen easily. An index finger is placed between the superior aspect of the first rib and the brachial plexus to protect the nerves, as a right angle clamp is passed over the superior aspect of the first rib to ensure that complete circumferential dissection has been achieved. The right angle clamp is spread widely, resecting a 1-cm portion of the first rib in the midaxillary line (Figs. 26-23 and 26-24) so that the surgeon can push the

FIGURE 26-21 ■ Dissection and mobilization of the first rib.

FIGURE 26-20 ■ The incisions for a video-assisted thoracic surgery (VATS) first rib resection are shown (arrows). A 2-cm incision is made over the third intercostal space at the bottom of the hair line in the midaxillary line between the pectoralis and latissimus dorsi muscles. VATS is performed with a 5-mm, 30-degree thoracoscope introduced into the fifth intercostal space at the midaxillary line, where a chest tube is eventually introduced.

FIGURE 26-22 ■ The first rib is mobilized, and a right angle is shown dissecting along the superior and inferior aspect of the rib.

FIGURE 26-23 ■ A rongeur is used to resect a 1-cm portion of the first rib in the midaxillary line. This transection allows the rib to become destabilized to facilitate disarticulation.

FIGURE 26-25 ■ Disarticulation and removal of the first rib anteriorly from its sternal attachment.

FIGURE 26-24 ■ A 1-cm portion of the rib has been removed by the rongeur. The rib is now destabilized, allowing for easier disarticulation.

FIGURE 26-26 ■ Disarticulation and removal of the first rib posteriorly from its vertebral attachment.

rib caudally. This greatly facilitates complete mobilization of the rib to the sternum (anteriorly) and the vertebral bodies (posteriorly). Once the rib is completely mobilized, it is cut adjacent to the sternum anteriorly and disarticulated from the vertebral body posteriorly (Figs. 26-25 and 26-26). If there is difficulty with disarticulation, the rib is cut flush with the vertebral bodies posteriorly. Once the rib is completely removed, the axillary structures are easily visualized in their decompressed state (Fig. 26-27).

EFFORT THROMBOSIS: PAGET-SCHROETTER SYNDROME

Effort thrombosis of the axillary-subclavian vein (Paget-Schroetter syndrome) is generally secondary to unusual or excessive use of the arm in addition to the presence of one or more compressive elements in the thoracic outlet.^{46,57}

FIGURE 26-27 ■ Once the rib is completely removed, the axillary structures can be visualized in their decompressed state: (a) subclavian vein, (b) subclavian artery, (c) brachial plexus.

Historically, Paget⁵⁸ in 1875 in London and Von Schroetter⁵⁹ in 1884 in Vienna described this syndrome of thrombosis of the axillary-subclavian vein, which bears their names. The word *effort* was added to thrombosis because of the frequent association with exertion producing either direct or indirect compression of the vein.⁶⁰ The thrombosis is caused by trauma⁶¹ or is associated with unusual occupations requiring repetitive muscular activity, as has been observed in professional athletes, linotype operators, painters, and beauticians. The combination of cold temperature and traumatic factors, such as carrying skis over the shoulder, tends to increase the proclivity for thrombosis.⁶² Elements of increased thrombogenicity also increase the incidence of the problem and exacerbate its symptoms on a long-term basis.

In Paget-Schroetter syndrome, which is always secondary to TOS, the costoclavicular ligament congenitally inserts into the first rib much farther laterally than normal in all cases we have seen (Fig. 26-28 is normal; Fig. 26-29 is abnormal). Subsequent hypertrophy of the scalenus anticus muscle (e.g., in weightlifters), which is lateral to the axillary-subclavian vein, produces severe external compression of the vein. This establishes the abnormal anatomic structure that can produce vein occlusion—the Paget-Schroetter syndrome.⁶³

Adams and colleagues^{46,64} reported long-term results in patients treated conservatively with elevation of the

arm and warfarin sodium (Coumadin). There was a 12% incidence of pulmonary embolism. Development of venous distention occurred in 18% of patients, and late residual arm symptoms of swelling, pain, and superficial thrombophlebitis were noted in 68% of patients (deep venous thrombosis with postphlebotic syndrome). Phlegmasia cerulea dolens was present in one patient.

For many years, therapy included elevation of the arm and use of anticoagulants, with subsequent return to work. If symptoms recurred, the patient was considered for a first rib resection, with or without thrombectomy,⁶⁴ as well as resection of the scalenus anterior muscle and removal of any other compressive element in the thoracic outlet, such as the cervical rib or abnormal bands.⁶⁵⁻⁶⁷

Increased use of local thrombolytic agents,⁶⁸⁻⁷⁰ combined with prompt surgical decompression of the neurovascular compressive elements in the thoracic outlet,⁷¹ has reduced morbidity of Paget-Schroetter syndrome and the necessity for thrombectomy, and it has substantially improved clinical results, including the ability to return to work.⁵³

One advantage of urokinase over streptokinase is the direct action of urokinase on the thrombosis distal to the catheter to produce a local thrombolytic effect.⁷²⁻⁷⁴ Streptokinase produces a systemic effect that can potentially cause complications. Heparin is given postoperatively until the catheter is removed. Another advantage is that

FIGURE 26-28 ■ The cross-sectional view of the neurovascular structures traversing the thoracic outlet, with the clavicle above and the first rib below.

FIGURE 26-29 ■ The costoclavicular ligament inserts much farther laterally on the first rib, causing vein occlusion.

the need for thrombectomy is reduced by the use of a thrombolytic agent followed by aggressive surgical intervention because some of the long-term disability is due to the morbidity of a thrombectomy as well as recurrent thrombosis.⁷⁵⁻⁷⁷

The natural history of Paget-Schroetter syndrome suggests moderate morbidity⁷⁸⁻⁸⁰ with conservative treatment alone. Bypass with vein or other conduits⁸¹⁻⁸³ has a limited application in this low-pressure system. Causes other than TOS must be treated individually^{84,85} using the basic principles mentioned. Intermittent obstruction of the subclavian vein⁸⁶ can lead to thrombosis, and decompression should be used prophylactically.^{82,83} More than 600 patients with Paget-Schroetter syndrome underwent operations by Urshel. By far the best results were seen when the clots were lysed less than 6 weeks after the axillary-subclavian vein was occluded, and then the first rib was promptly removed and neurovascular decompression was provided. This technique uniformly gave good results. If the time of treatment is greater than 6 weeks from the time of the initial thrombosis, the results are less good, but the same procedure should be performed to obtain optimal results.^{47,87,88}

After successful thrombolysis, there often appears to be a stenosis in the vein on venography. Therefore, interventional radiologists or cardiologists sometimes dilate this vein, suspecting an “internal” problem rather than

seeing it as the result of external compression. Because the stenosis immediately closes down after balloon dilation, they may insert intravascular stents. These techniques have all failed in our experience⁸⁷⁻⁸⁹ and in the experiences of others.⁹⁰ In general, if the vein is not patent, then rib resection is not indicated.

DORSAL SYMPATHECTOMY FOR THORACIC OUTLET SYNDROME MANAGEMENT WITH VIDEO-ASSISTED THORACIC SURGERY

Dorsal sympathectomy and the management of TOS are significantly improved with video assistance through magnification and improved video systems. An open transaxillary approach for TOS can be slow, exposure can be challenging, and can require someone to lift the arm up for a protracted time. Video-assisted thoracic surgery addresses these issues. A VATS view from inside the pleura offers excellent visualization of anatomic structures, does not require anyone to lift the arm, and comes with an additional bonus of excellent visualization for other members of the team, which is particularly helpful for surgical residents. In addition, for sympathectomy

alone, VATS offers less pain to the patient and a shorter hospitalization.

Video assistance is used in two techniques. One technique involves the sympathectomy through two ports, with the standard VATS. The second technique involves a transaxillary incision with removal of the first rib using video-assistance magnification and light; the surgeon operates either directly or secondarily while visualizing the image on the television screen. This last technique was popularized by Martinez.⁹¹

The primary indications for dorsal sympathectomy include hyperhidrosis, Raynaud phenomenon and Raynaud disease, causalgia, reflex sympathetic dystrophy (RSD), and vascular insufficiency of the upper extremity. Except for hyperhidrosis, all these indications require the usual diagnostic techniques, including cervical sympathetic block to assess whether the symptoms are relieved by temporary blockade of the sympathetic ganglia. When Raynaud phenomenon of a minor to moderate degree is associated with TOS, the simple removal of the first rib with any cervical rib, in addition to stripping the axillary-subclavian artery (neurectomy), will relieve most symptoms after the initial operation.⁴⁰

It is rarely necessary to perform a sympathectomy unless Raynaud disease is a very severe type, in which case a dorsal sympathectomy is performed with first rib resection. In contrast, for patients with recurrent TOS and causalgia, dorsal sympathectomy should be performed with the initial reoperation procedure.^{37,39}

Pathophysiology

The principal physiologic effect expected of sympathectomy is the release of vasomotor control and hyperactive tone of the arterioles and smaller arteries that have a muscular element in the vessel wall. Circulation to the skin, peripheral extremity, and bone receives major improvement, but the effect on skeletal muscle of the arm is minimal. The other known function is the reduction of cutaneous sweating, when it is profuse and undesirable. Sympathectomy is often associated with compensatory sweating. RSD is associated with pain, neurasthenia, and cutaneous atrophy (Sudeck-Leriche) and posttraumatic limb. These patients also benefit from a sympathectomy if a diagnostic block is effective. Sympathectomy is not recommended for patients with diabetic neuropathy. Nor should it be performed in any of the vascular vasospastic syndromes until after conservative management, including cessation of tobacco products and institution of β -blockers, peripheral vasodilators, and calcium channel blockers, has failed.⁹²

Preganglionic sympathetic nerves derived from the spinal cord do not follow a corresponding relationship to the accompanying somatic nerves. The cervical ganglia of C1 to C4 are fused into a superior cervical ganglion, C5 and C6 into the middle cervical ganglion, and C7 and C8 into the inferior ganglion, which combines with the ganglion from T1 to the larger stellate ganglion. Cervical ganglionectomy is not used for denervation of the upper extremity, because the preganglionic sympathetic outflow from the spinal cord to the arm is usually from T2

through T9, mostly from T2 through T4. In approximately 10% of cases, T1 preganglionic fibers also supply the upper extremity. For removal of preganglionic fibers to the upper extremity in most patients, removal of paravertebral ganglia T2 and T3 with the interconnecting chain is sufficient. Postganglionic fibers from these two segments often join and branches then follow the nerves of the brachial plexus. The joined T2 and T3 fibers that bypass the stellate ganglion are known as the nerve of Kuntz.⁹³ For the remaining patients who have a T1 connection through the stellate ganglion to obtain adequate sympathetic denervation, the lower third of the stellate ganglion should also be removed, as recommended by Palumbo.^{94,95}

Patients with RSD or sympathetic maintained pain syndrome (SMPS) must complain of pain outside a peripheral nerve distribution.⁹⁶ Although the injury itself may have been minor, the pain appears out of proportion to the injury. We have seen two types of RSD or SMPS. One type involves the hand or even a greater majority of the upper extremity, and a second is localized to one or more digits. In no instance can the patient's pain be completely accounted for by an injury to a specific nerve, although injury to a specific nerve may cause the more diffuse symptoms. The patient also demonstrates diminished hand function. Several patients have been referred with a diagnosis of SMPS, and, on examination, it is apparent that although they may complain of diffuse pain, the hand functions normally with a full range of movement, and motor power is demonstrated. These patients, of course, do not have SMPS. The patient must also demonstrate some joint stiffness. The skin and soft tissue trophic changes demonstrate varying amounts of vasomotor instability, depending on the stage of SMPS.

According to Mackinnon and Dellon,⁹⁶ there are early, intermediate, and late stages of SMPS. In the early stages, vasomotor instability is noted with dramatic sympathetic overactivity apparent in the hand or digit involved. Instability, with symptoms varying between redness and warmth and cyanosis and sweating, is noted in this early stage. Edema is also a classic finding in the early stage. In the intermediate stage of SMPS, pain is a less dramatic component and is usually elicited by attempts to move the joints. At rest, the patient may be comfortable. The edema and vasomotor changes have settled by this time, and the hand has the appearance of a "burned out" dystrophic hand, with marked stiffness and atrophy of the soft tissue noted. The normal wrinkles on the dorsum of the hand are no longer apparent. The fingertips may have a tapered appearance. The nail growth is usually more exaggerated than in the normal hand, and the hand is often cool and pale. The intermediate stage extends over a number of months. During the late stage, all the superimposed problems of disuse atrophy may take effect. During this stage, problems with the elbow and shoulder are common, although the initial SMPS involved only the hand or one or more digits. The degree of pain experienced during the late phase is variable and is often the result of disuse and stiffness. SMPS can affect other areas of the body and has been observed in the foot, face, and penis.

Complications

Horner Syndrome

If the fibers of C7 and C8 (the upper part of the stellate ganglion) are removed, Horner syndrome results. This syndrome involves miosis, enophthalmos, drooping of the eyelid (ptosis), and flushing of that side of the face, with loss of sweating in that area.⁹⁷ Currently, sympathectomy procedures are usually not performed at the level of the second rib or higher so that the risk of Horner syndrome is low.

Postsympathectomy Neuralgia

The complication of postsympathectomy neuralgia is less common in the upper extremities than in the lower extremities. The pain usually occurs in the shoulder and upper arm on the lateral aspect. Clinical history usually substantiates this diagnosis if the symptoms occur within the first 3 months. The confirmation can be obtained with a test involving skin resistance and sudomotor activity detection. Test results reveal increased sympathetic activity and suggest a rebound phenomenon from the nonsympathectomized adjacent dermatomes. Rebound may be a regeneration of nerve fibers or an increased response of peripheral nerves to catecholamines. Symptoms usually resolve in 3 to 6 weeks with conservative management. Phenytoin sodium (Dilantin), carbamazepine (Tegretol), and calcium-channel blockers are all used in the medical management of these symptoms.⁹⁸

Recurrent Symptoms

Occasionally, after an excellent sympathectomy, with a warm hand and good circulation, recurrent symptoms occur as early as 3 months. These symptoms may be secondary to the regeneration or sprouting and rehooking of nerves, or to failure to strip the sympathetic nerves from the artery and the transfer of sympathetic tone through these nerves. Therefore, stripping of the axillary-subclavian artery of its local sympathetic nerves is performed in each case at the initial operation.⁹⁹ In addition, during the initial procedure, cauterization of the bed of the sympathectomy area produces sympathetic effects that usually last at least 3 years. We have also had good success with redo sympathectomy if symptoms recur after the initial procedure.

Surgical Approaches for Dorsal Sympathectomy

Historically, the anterior cervical approach has been used, with the division of the scalenus-anticus muscle as the approach to the cervical sympathetic chain.⁵⁹ The stellate ganglion lies on the transverse process of C6, and this approach is used primarily by neurosurgeons and vascular surgeons. For hypertension, Smithwick¹⁰⁰ and Urschel and Razzuk¹⁰¹ popularized the posterior approach using a longitudinal parasternal incision with the patient in the prone position. A small piece of both the first and the

second rib is removed and the sympathetic chain is identified in the usual position. This approach has the advantage of allowing bilateral procedures at the same time without changing the patient's surgical position, but with the advent of VATS, this approach is only of historic interest.

Another approach is the transaxillary transthoracic approach, which is performed through the second or third interspace with the transverse subhairline incision.^{94,95,102,103} This approach is more painful for the patient than others, but with VATS, it can be performed with minimal discomfort. The approach used most frequently when the patient also has TOS is the transaxillary approach, with resection of the first rib, retraction of the pleura caudad, and a dorsal sympathectomy.^{40,55} This combined procedure causes minimal pain and low morbidity. Video assistance is used frequently for this approach as well.

Variations of Dorsal Sympathectomy

Standard sympathectomy involves removal of the sympathetic chain with thoracic ganglia 1, 2, and 3. This approach involves removing the lower third of the stellate ganglion⁴⁰ with the second and third ganglia and the interconnecting sympathetic chain. This is the standard approach for Raynaud phenomenon, causalgia, and RSD. The standard VATS approach for hyperhidrosis involves either a 1-cm incision in the axilla or two 3-mm trocars for insufflation and transection of the nerve. The Society of Thoracic Surgeons workforce on sympathectomy recommends transecting the sympathetic chain at the third rib.¹⁰⁴ Horner syndrome occurs after removal of C8 or the upper two thirds of the stellate ganglia. Complete dorsal sympathectomy includes the removal of the lower third of the stellate ganglion and the sympathetic chain at the second and third ribs. This procedure is primarily for patients with ulceration of the fingers associated with Raynaud disease. Previous evidence suggests that removal of only the T2 and T3 ganglia, avoiding the stellate ganglia altogether, offers adequate sympathectomy for the standard indications of hyperhidrosis, Raynaud phenomenon, causalgia, and RSD. That was not Urshel's experience, because careful attention to anatomy virtually eliminates the possibility of Horner syndrome; thus, he believed that there is no advantage in leaving T1 for the treatment of ulcerations associated with Raynaud disease. Currently, the operation is performed at the third rib, plus the fourth rib if there is significant axillary or plantar sweating.¹⁰⁴

Technique

Two approaches are used for sympathectomy to treat TOS. The first is the transaxillary approach with a transthoracic sympathectomy.¹⁰⁵ This involves leaving the first rib, collapsing the lung, and performing the sympathectomy with video-assisted technique.¹⁰⁶ The second is a transaxillary removal of the first rib and the retraction of the pleura with a dorsal sympathectomy, which was used in most patients.

Urshel Transaxillary Approach with a Transthoracic Sympathectomy

The patient is placed in the lateral thoracotomy position with an axillary roll under the downside arm. The upper arm is suspended at 90 degrees from the chest wall over a pulley system with a 1-lb (453-g) weight.¹⁰³ An arm holder is used to ensure that no hyperabduction or hyperextension of the shoulder occurs and that relaxation occurs every 3 minutes. Three ports are used between the second and the fourth interspaces. The camera should be placed either anteriorly or in the midaxillary port. A double-lumen endobrachial tube is used, and the upside lung is collapsed, ventilating only the downside lung.¹⁰⁷ This selectively shunts blood through the downside lung, and excellent oxygenation usually results.

The lung is retracted and the sympathectomy is performed. The mediastinal pleurae are cut open and the sympathetic chain is identified on the vertebral body near the neck of the ribs. Nerve hooks are used to elevate the dorsal sympathetic chain; the nerve connections, including the gray and white rami, are clipped before transection or cauterization. The stellate ganglion is divided at the junction of the lower third and upper third, where it looks like a cat's claw. The stellate ganglion is cut, but it is not photoablated or cauterized, because Horner syndrome can result from either heat or light injury to the adjacent C8 ganglion. The lower ganglia can be cauterized, photoablated with the laser, or cut. Hemostasis can be achieved with the cautery, but its use is usually minimal to reduce the chances of Horner syndrome. The pleurae are left open and a chest tube is placed through one of the ports for drainage. There is a curvature of the sympathetic chain, so in many cases the stellate ganglion lies transversely, rather than vertically, on the transverse process of the vertebral body. Special knowledge of the anatomy is important, especially the location of the thoracic duct, which can simulate the sympathetic chain and be injured if not appropriately identified.

Urshel Transaxillary First Rib Resection for Thoracic Outlet Syndrome with Retraction of the Pleura and Sympathectomy

This technique differs slightly from other VATS procedures in that an actual incision is made transversely below the axillary hairline and the technique for rib resection is carried out. A right-angle breast retractor with a light is used, and a Dever retractor is placed on the other side of the incision. The video camera is a standard thoracoscope, a Wolf scope, or an Olympus flexible operating esophagogastroscope.

The pleurae are retracted inferiorly using a sponge stick, and the sympathetic chain is identified on the transverse process of the vertebral bodies. It is vertical between the T2 and T3 ganglia. However, T1, the lower part of the stellate ganglion, angles anteriorly and lies in almost a transverse position. Clips are placed on all the communicating rami of the sympathetic chain. T2 and T3 ganglia are resected. The stellate ganglion is divided at the junction of its lower third, and T1 is removed. This division is made with a sharp knife. Cauterization or laser

photoablation is not used in the stellate ganglion. Cautery is used after the removal of the sympathetic chain to prevent sprouting. Hemostasis is secured. A large, round Jackson-Pratt drain is placed, and methylprednisolone acetate (Depo-Medrol) is injected over the nerve roots and plexus that have undergone neurolysis. The camera is removed and the wound is closed in the usual manner.

Results

In 926 patients, sympathectomy alone or in conjunction with first rib removal for TOS has been successful.¹⁰⁸ In only six patients has sympathetic activity recurred in less than 6 months. All these patients were initially treated conservatively. Three of the six patients required repeated sympathectomy. Postsympathectomy neuralgia occurred in only 2 of 926 patients. Both patients were managed successfully in a conservative manner. Among the patients in whom Horner syndrome was not created deliberately, four patients developed the syndrome. All resolved spontaneously in several months. Forty-two cases of Raynaud phenomenon were treated successfully with first rib resection alone or with periarterial neurectomy without initial sympathectomy.^{47,89}

REOPERATION FOR RECURRENT THORACIC OUTLET SYNDROME

Extirpation of the first rib relieves symptoms in patients with TOS not relieved by physiotherapy. Of the surgically treated patients, 10% develop various degrees of shoulder, arm, and hand pain and paresthesias that are usually mild and short-lasting and that respond well to a brief course of physiotherapy and muscle relaxants. In a few patients (1.6%), symptoms persist, become progressively more severe, and often involve a wider area of distribution because of entrapment of the immediate trunk in addition to the lower trunk and C8 and T1 nerve roots. Symptoms can recur 1 month to 7 years after rib resection; in most patients, they recur within the first 3 months. Symptoms consist of an aching or burning type of pain, often associated with paresthesias, involving the neck, shoulder, parascapular area, anterior chest wall, arm, and hand. Vascular lesions are uncommon and consist of causalgia minor and an occasional injury of the subclavian artery with subsequent false aneurysm formation caused by the sharp edge of a remaining posterior stump of an incompletely resected first rib (Fig. 26-30). Recurrence is diagnosed on the basis of history, physical examination, and decreased nerve conduction velocity across the outlet. Diagnostic evaluation should also include thorough neurologic evaluation, chest and cervical spine radiography (Fig. 26-31), cervical myelography, subclavian artery angiography, and magnetic resonance imaging of cervical spine and brachial plexus,¹⁰⁹ when indicated.

Two groups of patients who require reoperation can be identified. Pseudorecurrence occurred in patients who did not have relief of symptoms after the initial operation. These patients can be separated etiologically as those in whom the second rib was mistakenly resected instead of

FIGURE 26-30 ■ Arteriogram showing a false aneurysm of the right subclavian artery caused by the pointed end of a posterior stump (arrow) of an incompletely resected first rib.

FIGURE 26-31 ■ Cervical film showing a posterior remnant (arrowhead at lower right) of an incompletely resected first rib in a patient who developed recurrent thoracic outlet syndrome.

the first; the first rib was resected, leaving a cervical rib; a cervical rib was resected, leaving an abnormal first rib; or a second rib was resected, leaving a rudimentary first rib. True recurrence occurred in patients whose symptoms were relieved after the first operation but who retained a significant segment of the first rib or who had complete resection of the first rib but showed excessive scar formation around the brachial plexus.

Physiotherapy should be given to all patients with symptoms of neurovascular compression after first rib

resection. If the symptoms persist and the conduction velocity remains below normal, reoperation is indicated.

Reoperation for TOS is performed with the posterior thoracoplasty approach to provide better exposure of the nerve roots and brachial plexus, to thus reduce the danger of injury to these structures and to provide adequate exposure of the subclavian artery and vein. This incision also provides a wider field for resection of any bony abnormalities or fibrous bands and allows extensive neurolysis of the nerve roots and brachial plexus, which is not always possible with the limited exposure of the transaxillary approach. The anterior or supraclavicular approach is inadequate for reoperation.

The basic elements of reoperation include resection of persistent or recurrent bony remnants of a cervical first rib, neurolysis of the brachial plexus and nerve roots, and dorsal sympathectomy. Sympathectomy removes T1, T2, and T3 thoracic ganglia. Care is taken to avoid damage to the C8 ganglion (upper aspect of the stellate ganglion), which produces Horner syndrome. The reoperation provides relief of major and minor causalgia and alleviates the paresthesias in the supraclavicular and infraclavicular areas. The incidence of "postsympathetic" syndrome has been negligible in this group of patients. A nerve stimulator is used to differentiate scar from nerve root to avoid damage with reoperations in these patients.

OPERATIVE TECHNIQUE FOR REDO THORACIC OUTLET SYNDROME SURGERY

The technique of the operation includes a high thoracoplasty incision that extends from 3 cm above the angle of the scapula, halfway between the angle of the scapula and the spinous processes, and caudad 5 cm from the angle of the scapula. The trapezius and rhomboid muscles are split the length of the incision. The scapula is retracted from the chest wall by making a subperiosteal incision over the fourth rib. The posterior superior serratus muscle is divided, and the sacrospinalis muscle is retracted medially. The first rib remnant and cervical rib remnant, if present, are located and removed subperiosteally. After the rib remnants (Fig. 26-32) have been resected, the regenerated periosteum is removed (Fig. 26-33). In our experience, most regenerated ribs occur from the end of an unresected rib segment rather than from periosteum, although the latter is possible. For a reduction in the incidence of bony regeneration, it is important in the initial operation to remove the first rib totally in all patients with primarily nerve compression and pain.

If there is excessive scar after removal of a bony rib remnant, it may be prudent to do the sympathectomy initially. A 1-inch segment of the second rib is resected posteriorly to locate the sympathetic ganglion. In that way, the first thoracic nerve may be easier to locate below rather than through the scar.

Neurolysis of the nerve root and brachial plexus is done with a nerve stimulator and is carried down to, but not into, the nerve sheath. Neurolysis is extended peripherally over the brachial plexus as far as any scarring persists. Excessive neurolysis is not indicated, and opening of the

FIGURE 26-32 ■ A long posterior remnant (arrow) of an incompletely resected first rib in a patient with recurrent thoracic outlet syndrome.

FIGURE 26-33 ■ Fibrocalcific band (two black arrows) of regenerated periosteum in continuity with a posterior remnant (white arrow) of the first rib in a patient with recurrent thoracic outlet syndrome.

nerve sheath produces more scarring than it relieves. For scarring to be minimized, the initial operation for TOS should include complete extirpation of the first rib, avoidance of hematomas with adequate drainage either by catheter or by opening the pleura, and avoidance of infection.

The subclavian artery and vein are released if symptoms indicate. The scalenus medius muscle is débrided. The dorsal sympathectomy is completed by extrapleural dissection. Meticulous hemostasis is achieved, and a large, round Jackson-Pratt catheter drain placed in the area of, but not touching, the brachial plexus is brought out through the subscapular space via a stab wound into the axilla. SeptraSeal (hyaluronidase) and methylprednisolone acetate (Depo-Medrol; 80 mg) are left in the area of the brachial plexus, but the patient is not given systemic steroids unless keloid formation has occurred. The wound is closed in layers with running Vicryl. Range-of-motion exercises are performed to prevent shoulder limitation, but overactivity is avoided to minimize excessive scar formation.

When the problem is vascular and involves false or mycotic aneurysms, special techniques are used for reoperation. A bypass graft is interposed from the innominate

or carotid artery proximally, through a separate tunnel distally, to the brachial artery. The graft is usually performed with the saphenous vein, although other conduits may be used. The arteries supplying and leaving the infected aneurysm are ligated. Subsequently, the aneurysm is resected by a transaxillary approach with no fear of bleeding or ischemia of the arm.

Special instruments have been devised to provide adequate resection through the transaxillary or posterior route. These instruments include a modified strengthened pituitary rongeur and a modified Leksell double-action rongeur for removal of the first rib without danger to the nerve root.

The sympathectomy relieves chest wall pain that resembles angina pectoris, esophageal disease, or even a tumor in the lung by denervating the deep fibers that accompany the arteries and bone.

The results of reoperation are good if an accurate diagnosis is made and the proper procedure is used.⁴⁰ More than 1200 patients have been followed for 6 months to 15 years. All patients improved initially after reoperation, and in 79%, the improvement was maintained for more than 5 years. In 14% of the patients, symptoms were managed with physiotherapy; 7% required a second reoperation, in every case because of rescarring. There were no deaths, and only two patients had infections that required drainage.¹⁰⁷

SUMMARY

Thoracic outlet syndrome is recognized in approximately 8% of the population. Its manifestations may be neurologic, vascular, or both, depending on the component of the neurovascular bundle predominantly compressed. The diagnosis is suspected from the clinical picture and is usually substantiated by determination of the UNCV. Treatment is initially conservative, but persistence of significant symptoms, which occurs in approximately 5% of patients with diagnosed TOS, is an indication for first rib resection. Primary resection is performed preferably through the transaxillary approach; however, VATS, supraclavicular, and posterior approaches are all reasonable.

It can be argued that overall there is no significant difference in outcomes and complications between the most widely accepted approaches and that neither is clearly superior to the other.¹¹⁰⁻¹¹³

As such, surgeon preference, comfort, and mastery of the technique are integral to optimizing outcomes with the chosen approach. Symptoms of various degrees recur after first rib resection in approximately 10% of patients. Most patients improve with physiotherapy, and only 1.6% require reoperation. Reoperation for recurrent symptoms is performed through a high posterior thoracoplasty incision.^{37,107}

Acknowledgments

Dr. Urschel was a leader in the treatment of TOS, and his contributions to the topic will aid in the education of many current and future surgeons. The crux of his input

into this chapter has been preserved with updates added, where appropriate. He will be missed. In addition, we are grateful to Rachel Montano and Brenda Knee for their assistance in organizing, preparing, and transcribing the original chapter.

SPECIAL CONSIDERATIONS

Secondary Spontaneous Pneumothorax

Catamenial Pneumothorax

The term *pneumothorax* was first coined by Jean Marc Gaspard Itard¹ in 1803, when he called attention to five cases in which free air was found in the thorax after trauma. Derived from the Greek words *pneuma* (air) and *thorakos* (breastplate or chest), it is an apt description for the accumulation of air in the pleural space that leads to partial or total collapse of the affected lung. The clinical features of pneumothorax were first described in 1819 by René Laennec,² who postulated the relationship to pre-existing blebs and unprovoked rupture and, hence, the term *spontaneous pneumothorax*. This pathophysiologic mechanism was confirmed by Kjærgaard³ in later decades. Today, the classification of pneumothoraces is based on clinical presentation and underlying lung disease. Multiple management strategies range from simple evacuation of air from the pleural space to potential prevention of future pneumothoraces.

EPIDEMIOLOGY

Spontaneous pneumothorax (SP) may be termed either a primary or secondary event, dependent on underlying lung disease. Primary spontaneous pneumothorax (PSP) typically occurs in young patients with localized blebs but otherwise normal lungs. Secondary spontaneous pneumothorax (SSP) occurs in patients with marked structural lung disease and directly contributes to SP. Approximately 20,000 new cases of PSP are diagnosed annually in the United States,⁴ with an estimated economic impact of \$130 million per year in lost wages. The annual estimated incidence of PSP is between 7.4 and 18 cases per 100,000 population among men and between 1.2 and 6 cases per 100,000 population among women.⁴ Patients prone to PSP are usually tall and thin and between 10 and 30 years of age.⁵ A significant factor is cigarette smoking, which can increase the risk of PSP by a factor as high as 20.⁶

SSP develops as a complication of underlying lung disease, most commonly chronic obstructive pulmonary disease (COPD).⁷ The annual incidence of SSP is approximately 6.3 cases per 100,000 population among men and 2 cases per 100,000 population among women.⁴ The peak incidence occurs between the ages of 60 and 65 years.⁵

CAUSES

PSP manifests without forewarning signs or symptoms and is most likely caused by rupture of a subpleural bleb. This premise is based on cumulative results of patients undergoing computed tomography (CT), which demonstrated subpleural blebs in as many as 80%.^{8,9} Surgical experience confirmed the presence of bullae in more than 75% of patients who underwent video-assisted thoracoscopic surgery (VATS) and thoracotomy.¹⁰⁻¹² Recent research may indicate a more diffuse pathologic etiology than simple bleb rupture. Fluorescein-enhanced pathologic assay of resected lung tissue in PSP patients reveals significant inflammatory changes and potential air-leak sites remote from blebs and other visible abnormalities.¹³

After the first episode of PSP, recurrence varies, ranging from 16% to 54%. Most studies indicate an average of 30%.^{14,15} Recent research indicates that the presence of subpleural blebs on high-resolution CT confers a recurrence risk of up to 68.1%, whereas the absence of blebs carries a recurrence risk of only 6.1%.¹⁶ Most recurrences develop between 6 months and 2 years after the initial episode.¹⁵ Men who are tall and have a history of smoking are at the greatest risk of recurrence. Counseling for smoking cessation should be strongly encouraged.¹⁵ After the second episode of PSP, the likelihood of recurrence increases markedly and can reach as high as 83%.^{7,14}

CLINICAL PRESENTATION

PSP typically manifests with sudden pleuritic chest pain and dyspnea.^{6,17} Classic findings on physical examination include diminished breath sounds, hyperresonance, and fremitus; however, patients with small pneumothoraces may have normal findings on physical examination. Most patients with PSP are stable, primarily because of their young age and otherwise normal lung function. Patients with SSP are more likely to present with respiratory distress, a result of respiratory compromise caused by SP superimposed on preexisting lung disease.¹² Whereas tension SP is unusual, indicators include tachycardia, cyanosis, and hypotension.

IMAGING

Chest radiography is the most common diagnostic tool for SP. A thin pleural line can be identified that has been displaced from the chest wall. A small SP may be difficult to identify on plain radiography; an expiratory view may prove more beneficial in determining the presence of SP. Frequently, attempts are made to measure the size of the SP as a percentage of the hemithorax it occupies, although this method is typically inaccurate.^{18,19} On occasion, a giant bulla can mimic a pneumothorax. Subtle lines demarcate a bulla, which tends to be surrounded by thickened visceral pleura. In addition, a pleural line can frequently be seen with lung markings visible beyond the suspected bulla (double wall sign).^{20,21}

Controversy exists about the significance of routine chest CT to evaluate for subpleural blebs. Proponents contend that identification of large or multiple subpleural blebs on CT is an indication for early surgical intervention to prevent recurrence.^{11,22,23} Opponents of this principle argue that management should not be influenced by these findings alone.^{24,25} Although CT is seldom required for routine diagnosis of SP, when subpleural blebs are diagnosed on CT, recurrence rates are high and some will elect early intervention such as bleb resection.¹⁶

MANAGEMENT

Algorithms for the management of SP range from established management protocols (American College of Chest Physicians [ACCP] Consensus Statement) to operative intervention (Table 27-1). Selected therapies depend on a number of variables: SP size, stability of the patient, symptom complex, initial SP onset or recurrent episode, and presence or absence of structural lung disease.^{19,26} The principal procedure is evacuation of air from the pleural space (spontaneous resolution versus instrumentation). Additional procedures targeted to prevent future SP episodes may also be considered in cases of SP recurrence.

Observation

Small pneumothoraces are those that are less than 3 cm in distance between the apical parietal pleura and the

TABLE 27-1 American College of Chest Physicians Delphi Consensus Statement on Spontaneous Pneumothoraces

Clinically stable with small pneumothorax	• Observation 3-6 hr • Follow-up CXR excludes progression: discharge and 1-2 day follow-up • Unreliable or impractical follow-up: observation 24 hr
Clinically stable with large pneumothorax	• Admission • Aspiration (or) tube thoracostomy • Heimlich valve (or) water seal • Highly reliable patients • May discharge to home with Heimlich valve with < 48 hr follow-up
Clinically unstable with large pneumothorax	• Admission • Tube thoracostomy (24-28 Fr) • Pneumothorax catheter and Heimlich valve • Acceptable in small subset of patients • If initial placement does not resolve instability: rapid conversion to suction/water seal device and standard chest tube
Management of persistent air leak	• >4 days • Consider VATS and pleurodesis • Recommends against sclerosing agents through chest tubes • Surgical risk prohibitive, or patient refuses surgery • Pleurodesis via chest tube • Talc slurry • Doxycycline
Recurrence prevention	• Treatment reserved for second spontaneous pneumothorax • Operative intervention • Apical bullae resected, if present • Abrasive pleurodesis • Talc slurry: acceptable (alternative sclerosants rarely acceptable in this setting) • Parietal pleurectomy: acceptable (weak consensus) • Chemical pleurodesis an acceptable alternative • Talc slurry • Doxycycline

CXR, Chest x-ray; VATS, video-assisted thoracic surgery.

From Baumann MH, Strange C, Heffner JE, et al: *Management of spontaneous pneumothorax: an American College of Chest Physicians Delphi consensus statement*. *Chest* 119:590-602, 2001.

thoracic cupula, with no lateral component. Asymptomatic patients should be managed expectantly²⁶⁻²⁸ by close monitoring, physical examination, continuous pulse oximetry, and repeated chest radiography within 3 to 6 hours. The ACCP recommends against the placement of chest tubes, or aspiration of small pneumothoraces. Our practice is to monitor patients in the hospital for a minimum of 24 hours. Even though some patients with stable radiographic features may be discharged from the hospital with follow-up within 12 to 24 hours,^{16,26} the potential for catastrophic consequences from a missed tension pneumothorax is a great risk.²⁹ Small pneumothoraces usually resolve without intervention, but

recurrence is possible. If chest radiography reveals that the SP is enlarging, immediate intervention is crucial.

Aspiration

Aspiration allows evacuation of pleural air and complete reexpansion of the lung. This technique can be applied even for larger pneumothoraces if the patient is stable. We prefer the Seldinger technique,^{30,31} which uses a small, single-lumen central line placed over the superior rib edge in the second interspace in the midclavicular line. A three-way stopcock and large syringe are used to aspirate until resistance is felt, usually signifying full lung expansion. Chest radiography is then performed to confirm the findings, and the catheter is removed.^{27,28,32-36} Commercially prepared kits with one-way valves (Heimlich valve)⁷ allow air to exit but prevent air entry. These valves can be left in place until full lung expansion is achieved. For more rapid resolution, however, it is our preference to perform tube thoracostomy with a small chest tube. Complications of aspiration, although rare, may include bleeding and possible lung injury. Reported success is higher in resolving PSP (66% to 83%) than for SSP (37%).^{27,35} SP that does not respond successfully to aspiration requires tube thoracostomy.

Tube Thoracostomy

Tube thoracostomy is recommended for patients with large or symptomatic SP and for most patients with SSPs. Patients with signs of a tension pneumothorax should be treated without hesitation, even before chest radiography is performed. Tube placement is through the fifth intercostal space in the midaxillary line. In our experience, as with chest tubes placed through port sites following VATS, there is no need to tunnel chest tubes placed at bedside.

A small chest tube can be difficult to direct to the apex of the chest, so a 28 Fr is preferable. The chest tube is left in place for 24 to 48 hours. Our practice is to place the chest tube on water seal once lung expansion has been confirmed. If an air leak persists and nonoperative management is preferred, a Heimlich valve can be placed. The patient can then be discharged for outpatient management. The efficacy of suction is debated, but there is no evidence that it speeds the resolution of SP. If it is used, it should be used judiciously.³⁷ Tube thoracostomy successfully resolves PSP in approximately 90% of patients for the first occurrence, 50% for the first recurrence, and 15% after a second recurrence.³⁸ For this reason, definitive management of SP recurrences will require either surgical intervention or chemical pleurodesis.

Pleurodesis

After tube thoracostomy, chemical pleurodesis may help prevent SP recurrence. Sclerosing agents are instilled to create pleural symphysis. The most commonly used agents are sterile talc slurry and doxycycline solution. Because adult respiratory distress syndrome may be triggered by high doses of talc, use should be limited to

5 g.^{39,40} In theory, talc has the potential to induce malignant transformation after decades of use, but thus far, this has not been demonstrated in humans.⁴¹ Nonetheless, our agent of preference is doxycycline to sclerose benign pleural processes. A total of 500 mg of doxycycline combined with lidocaine is infused through the chest tube, and the patient's position is shifted from side to side to distribute the sclerosant. Suction is then placed for 48 hours. Recurrence of SP in patients treated with bedside pleurodesis is high, ranging from 8% to 40%.^{40,42,43} In our institution, this treatment is reserved for patients who are not considered good operative candidates, most commonly patients with SSP.

Surgery

Surgical indications for PSP are recurrence, large or persistent air leaks, and incomplete lung expansion after tube thoracostomy. Other surgical indications include patients with a history of bilateral SP and patients in occupations that would place them at high risk if a pneumothorax recurred, such as commercial pilots and professional scuba divers.^{19,26,37,38} Although some thoracic surgeons recommend surgery in patients with a first-time PSP if bullae are detected on CT scan,²² we think that this strategy is highly aggressive, unnecessary, and unproven; thus we do not incorporate this practice into our treatment strategies.

VATS is the surgical procedure of choice for SP, replacing the previous procedure, axillary thoracotomy.^{44,45} The goals of surgery are resection of the offending bulla, complete lung expansion, and pleurodesis to prevent recurrence. A standard three-port VATS technique is used with lung isolation through a double-lumen endotracheal tube. The entire lung is carefully inspected, with particular attention to the apex and superior segments, because these are typical bullae locations. Saline flooding of the hemithorax during gentle lung inflation can help locate a ruptured bleb. Some surgeons resect the apex of the lung even if no bleb is located, although our practice is to perform lung resection only when a bleb is identified (Fig. 27-1). Buttressed staple lines are not necessary with otherwise normal lung parenchyma.

Intraoperative pleurodesis should be performed in addition to blebectomy. Mechanical pleurodesis is our most common method and is performed with use of a Bovie scratch pad with aggressive abrasion of the parietal pleura (Fig. 27-2). It is our practice to infuse doxycycline as an additional chemical sclerosant, although some surgeons choose to infuse talc at the time of surgery with good results and minimal impairment of pulmonary function over time.^{46,47} This is in spite of a recent study out of Korea suggesting that there is no difference in recurrence with mechanical pleurodesis following bleb resection.⁴⁸

Another effective method of obtaining pleural symphysis is parietal pleurectomy, by either VATS or open techniques. Results are similar to those of mechanical abrasion.^{49,50} Surgeons should make every effort to control air leak before leaving the operating room. Apical chest tube placement is crucial to full lung expansion. Postoperatively, chest tubes are placed to water seal as soon as

a chest x-ray demonstrates full expansion, and no air leak is present. VATS successfully resolves SP and prevents recurrence in more than 90% of patients.⁵¹ Whereas some studies show that recurrence of SP is slightly higher with VATS compared with thoracotomy, this small increment does not justify the discomfort and lost work days in this generally young population.⁵² Thoracotomy is reserved for VATS failures and complex giant bleb resections not amenable to VATS.

SPECIAL CONSIDERATIONS

Secondary Spontaneous Pneumothorax

Clinical presentation of SSP is similar to that of PSP; however, dyspnea and respiratory compromise are often more profound, given the presence of underlying lung

disease, even with small pneumothoraces. In this setting, intervention should be performed quickly with tube thoracostomy. Major causes of SSP are COPD with bleb rupture followed by *Pneumocystis* infection in patients with HIV infection, asthma, cystic fibrosis, necrotizing pneumonia, or tuberculosis. Less common causes are idiopathic pulmonary fibrosis, Langerhans cell histiocytosis, lung cancer, lymphangioleiomyomatosis, sarcoidosis, and catamenial pneumothorax.¹² SP in patients with COPD portends poor long-term prognosis.⁵³ Management strategies must be tailored to the individual patient. Operative risk in a markedly compromised patient must be weighed against the potential morbidity and prolonged hospital course that can accompany nonoperative intervention. We have found Heimlich valves particularly valuable in managing patients with prolonged air leak because they allow easy ambulation and outpatient management.

Catamenial Pneumothorax

Catamenial pneumothorax is a rare form of SP usually occurring within 72 hours of menstruation. The typical patient is between 30 and 40 years of age, although age may range substantially. Theories are unproven but suggest that catamenial pneumothorax is caused by congenital diaphragmatic fenestrations that allow passage of air through the peritoneum to the pleura or pathologic intrathoracic endometrial implants that cause perforation of the visceral pleura.^{54,55} Right-sided catamenial pneumothorax is more common, but the reasons for this are unclear. When catamenial pneumothorax recurs despite intervention, treatment can be challenging. Hormonal manipulation with gonadotropin-releasing hormone agonists has been recommended; however, side effects can be unpleasant, and it should be combined with surgery for optimal results.⁵⁵ Our approach is to inspect the diaphragm for fenestrations thoracoscopically. If they are identified, fenestrations should be closed. This should be combined with mechanical pleurodesis or pleurectomy. Hormonal manipulation for one or two menstrual cycles can be considered while awaiting complete pleural symphysis.⁵⁵

CONCLUSIONS

EPIDEMIOLOGY

In the United States, empyema is seen in approximately 60,000 patients annually, with a mortality rate of 15%.¹ Approximately 50% of empyemas in the United States today result from pneumonia. Pleural infection may also result from lung surgery, trauma, esophageal perforation, or transdiaphragmatic spread of an intra-abdominal infection. At least 40% of all patients hospitalized with pneumonia have an ipsilateral pleural effusion.¹ The average length of stay for patients with parapneumonic empyema in the United States was approximately 15 days and is shorter for children than adults. The in-hospital fatality rate was 7.2% in the NIS database and was lower for children (0.4%) than for adults older than 65 years (16.1%).²

HISTORICAL REVIEW

Empyema is most often used to refer to collections of pus in the space around the lungs (pleural cavity). The word is derived from the Greek word *empyein*, meaning “pus-producing.” Hippocrates first described the serious nature of thoracic empyema more than 2400 years ago.³ Even then, the need for surgical intervention was recognized, and open drainage was essentially the only treatment available until the late 19th century. Gotthard Bülow was among the first to use a closed method of drainage of infected pleural fluid, which he reported in 1891.⁴ It was not, however, a widely recognized treatment

option until the findings of the U.S. Army Empyema Commission led by Graham and Bell in 1918.⁵ The influenza epidemic of 1917-1919 resulted in a dramatic rise in the incidence of streptococcal empyema. During the early period of the epidemic, open thoracic drainage was commonly used in military hospitals to treat parapneumonic fluid. Often this was done early in the acute empyema phase, prior to the development of adhesions, and resulted in lung collapse and respiratory compromise. The early mortality rate from such a condition was 30.2% in this group of otherwise healthy, young men. A much better understanding of the pathology and evolution of empyema was obtained as a result of the Empyema Commission. As a result, with the use of closed drainage, the mortality rate for empyema dropped to 4.3%. The principles outlined by Graham, consisting of avoidance of open drainage during the acute phase and sterilization and obliteration of the infected space, constitute the fundamentals of modern therapy.⁶ With the discovery of effective antibiotics in the mid-20th century, the incidence of empyema was significantly reduced. The introduction of antibiotics, however, led to the emergence of resistant infections, polymicrobial infection, and partially treated empyemas. The incidence of streptococcal empyema decreased markedly with the introduction of antibiotics, and *Staphylococcus aureus* emerged as the predominant pathogen. More recently, gram-negative and anaerobic bacteria have become important pathogens. In spite of current medical advances, thoracic empyema continues to be a challenging problem, associated with significant morbidity and mortality.^{7,8}

BACTERIOLOGY

The bacteria traditionally associated with parapneumonic empyema are *Streptococcus pneumoniae*, *Streptococcus pyogenes*, *Staphylococcus aureus*, and, more recently, *Streptococcus anginosus* (formerly *Streptococcus milleri*). Anaerobes have been identified as sole or coexisting pathogens in 25% to 76% of cases. A recent review of the NIS database between 1996 and 2008 characterized the changing epidemiology of parapneumonic empyema in community hospitals across the United States. The largest increase in relative incidence of empyema occurred in young adults. The most serious cases of empyema were associated with staphylococcal infections. For patients older than 40 years, staphylococcal empyema had a significantly higher in-hospital mortality rate than those associated with other pathogens. The mortality rate was 8.9 for patients aged 40 to 64 with staphylococcal empyema compared to 4.4% to 6.1% for other pathogens. For individuals older than 65 years, the mortality rate for staphylococcal empyema was 21.8% versus 12% to 16% for other pathogens.²

Most empyemas were categorized as having unknown pathogens. Among the pathogen specified cases, staphylococcal empyema accounted for most of the increased incidence of empyema, and these patients had the longest lengths of stay and highest mortality rate. This increase in staphylococcal empyema has also been noted in previous studies involving tertiary care facilities.^{9,10}

The incidence of pneumococcal empyema has remained relatively stable in both children and adults. Infant vaccination with a seven-valent pneumococcal conjugate vaccine (PCV7) started in 2000.¹¹⁻¹⁴ Studies documented significant reductions in the incidence of pneumonia hospitalizations after the introduction of this vaccine.^{15,16} Overall, national rates of childhood pneumococcal empyema remained relatively stable during the study period. The introduction of a 13-valent pneumococcal conjugate vaccine in 2010 in the United States may provide protection against several pneumococcal serotypes commonly associated with empyema.^{17,18}

The number of parapneumonic empyemas classified as being caused by unknown pathogens has increased significantly. Defining the etiology of empyema is difficult, and it is unclear whether this increase is related to truly unknown organisms, to imperfect laboratory testing, or to the increased use of antibiotics prior to hospitalization. Some studies using molecular techniques have suggested that a significant percentage of culture-negative empyema may be caused by pneumococci, mainly serotype 1.¹⁹⁻²³ Although recent studies suggest *Streptococcus anginosus* may be a leading cause of empyema,²⁴⁻²⁶ it can be difficult to distinguish between streptococcal species. Mixed bacterial infections are found in some parapneumonic empyemas.²⁶

The cause of the observed increase in the incidence of empyema is not clear. Part of the increase may be related to the increased incidence of antibiotic-resistant pathogens. The increase in cases of staphylococcal empyema seems to correlate with the increase in methicillin-resistant organisms.^{27,28} *Streptococcus pneumoniae* is an

exception—the incidence of resistant pneumococcal disease decreased markedly following the introduction of PCV7.²⁹

PATHOGENESIS

Classically, the development of empyema occurs in three clinical stages: the exudative stage, the fibrinopurulent stage, and the organizing stage. When initially presented with an infectious organism, the pleura responds with edema formation, and exudation of proteins and neutrophils into the pleural space. Inflammatory cytokines result in increased pleural mesothelial and capillary cells permeability, resulting in an effusion. Activated by bacteria, mesothelial cells act as phagocytes and trigger an inflammatory cascade with the release of chemokines, cytokines, oxidants, and proteases. Polymorphonuclear cells are recruited.¹

Early in the exudative stage, bacterial growth may be minimal, and the exudate may be sterile. The rapidity of progression depends on the type and virulence of the organism, host defenses, and initiation of antibiotic treatment. Staphylococcal pneumonias are almost always associated with pleural effusions. With uncomplicated parapneumonic effusions, the pleural fluid has a pH greater than 7.20, relatively normal glucose levels, and lactate dehydrogenase (LDH) levels that, although elevated, are typically less than 3 times the upper limit of normal. Most patients with uncomplicated parapneumonic effusions respond to antibiotics alone.

Untreated exudative effusions may develop into fibrinopurulent effusions or complex parapneumonic effusions. The fibrinopurulent stage represents the deposition of fibrin on visceral and parietal pleural membranes and the formation of loculations. Ongoing phagocytosis and cell lysis result in pleural fluid with a pH less than 7.20, LDH levels more than 3 times normal, and low glucose. A complex parapneumonic effusion develops into a pleural empyema when the concentration of leukocytes becomes sufficient to form frank pus. Empyema fluid consists of fibrin, cellular debris, and viable or dead bacteria. As fibrin is deposited into the pleural space, lymphatic channels may become occluded, further increasing the amount of pleural fluid. The fibrin strands result in loculations of the pleural space, which prevent drainage of the pleural fluid using a single needle or tube.³⁰ This stage is more likely to result in a positive Gram stain and/or positive bacterial cultures. This stage of pleural effusion requires catheter drainage and often surgical drainage.

The third and final phase is the organizing phase. This stage is characterized by the influx of fibroblasts and the formation of a thick, fibrous pleural peel along with continued maturation of dense septations. Both the visceral and the parietal pleura may become severely thickened with significant fluid remaining in the pleural space. During this stage of disease, simple drainage of the fluid may be possible, but the thick peel prevents reexpansion of the underlying lung. Failure of the “trapped” lung to reexpand will not allow for improved aeration of the lung or any improvement in breathing. The residual space quickly refills with infected fluid.

DIAGNOSIS: CLINICAL SIGNS AND SYMPTOMS, FLUID ANALYSIS, AND RADIOLOGIC APPEARANCE

The clinical presentation may vary depending on the underlying bacterial cause. Patients with aerobic infections tend to be more acutely ill with an initial presentation similar to that of pneumonia. This can be followed by a nonresolving picture with pleuritic chest pain, fever spikes, and failure to improve after receiving appropriate antibiotic therapy. Immunocompromised patients, older adults, and those with anaerobic infections may have a more indolent course and may experience weight loss, cough, fever, and anemia.²⁵ The pleural effusions are generally evident on upright chest radiographs. Lateral decubitus films are useful in determining whether the fluid is free flowing and amenable to complete percutaneous drainage.

The presence of leukocytosis, radiographic evidence of a pleural effusion, and the presence of purulent fluid on thoracentesis are classic findings of empyema. Signs or symptoms of infection, history of malignancy, or associated medical diseases such as cardiac failure or kidney or liver disease can be helpful in determining the cause of an effusion.

Ultrasound can detect loculations and can determine an appropriate site for thoracentesis. A computed axial tomographic (CAT) scan can determine the size and the location of the effusion and provides information regarding associated underlying parenchymal and pleural abnormalities. A CAT scan with intravenous contrast can further characterize the empyema, suggesting loculations or a thickened pleura or rind. Inspection of the lung-fluid interface may suggest entrapped lung and may reveal an underlying parenchymal process such as an abscess or tumor. The appearance of the effusion and fluid-lung interface can give indications as to the need for operative intervention (Figs. 28-1 to 28-4).

Thoracentesis is useful in determining the cause of an effusion. Pleural fluid evaluation should include a cytologic evaluation, pH level, gram stain and culture, cell

FIGURE 28-2 ■ CT scan of patient who required open decortication. The nonlayering of the effusion and the thickened visceral pleura peel suggest that extensive decortication may be required.

FIGURE 28-3 ■ CT scan showing separate basilar loculations of fluid, suggesting the need for intraoperative drainage.

FIGURE 28-1 ■ CT scan of a patient who required VATS decortication. The lenticular, loculated appearance suggests intraoperative drainage is required.

FIGURE 28-4 ■ CT scan showing an uneven, lobulated, circumferential effusion suggesting the presence of a thickened visceral peel that requires operative drainage and decortication.

count, and total protein, glucose, and LDH levels. Effusions are classified as exudative or transudative based on protein and LDH levels. Exudate effusions will have a pleural fluid protein/serum protein level higher than 0.5 and a pleural fluid LDH/serum LDH level higher than 0.6. The presence of an increased white blood cell count in the pleural fluid, particularly with a preponderance of neutrophils, may indicate pleural infection. Low pleural fluid glucose and a pH less than 7.20 are indicators of active pleural infection and the need for pleural drainage.

TREATMENT

Initial antibiotic coverage of patients with parapneumonic effusions is generally dictated by treatment guidelines for pneumonia and may be modified according to blood and pleural fluid microbial cultures and sensitivities. Empiric anaerobic antibiotic coverage may be initiated although anaerobes are much less likely to be cultured. Patients with nosocomial empyema need adequate gram-negative coverage. Vancomycin may be added for suspected methicillin-resistant infection. Reported bacteriology of pleural sepsis varies significantly between community acquired and nosocomial infections.³⁰ Early appropriate antibiotic therapy represents the cornerstone of therapy for pneumonia and parapneumonic effusion. Minimal size free-flowing effusions may be observed without a diagnostic aspiration because the risk of a complicated course is remote. All other free-flowing effusions should be aspirated for diagnostic purposes.

Uncomplicated parapneumonic, exudative effusions that are of small volume, free flowing without loculations, with a negative Gram stain, pH greater than 7.20, and negative cultures are usually inflammatory in nature. Most of these resolve with antibiotic treatment of the underlying pneumonia and can be observed without formal drainage.¹ Early drainage of pleural fluid becomes necessary when a parapneumonic effusion advances beyond the exudative stage to the fibrinopurulent stage and becomes a complicated parapneumonic effusion. Indications for immediate drainage are large effusions (larger than half the hemithorax), effusions with loculations, pH less than 7.20, positive Gram stain or culture, and low glucose levels. The presence of frank pus on aspiration is also an indication for immediate and complete drainage.¹

Options for drainage include serial thoracenteses, tube thoracostomy (with or without intrapleural fibrinolytics), thorascopic drainage, thoracotomy and drainage (decortication), and chronic open drainage. Choice of drainage is dependent on the viscosity of the pleural fluid; location, volume, and extent of loculations; and the general condition of the patient.

In theory, in the absence of loculations, either thoracentesis or tube thoracostomy should adequately drain any fluid. With significant ongoing infection and inflammation, however, continued production of fluid will occur, requiring repeat thoracentesis. Serial

thoracenteses are generally not recommended. Using such strategy, one study showed that the average patient required 7.7 aspirates with an average hospital stay of 31 days.³¹ Tube thoracostomy is generally performed with a size 24 to 32 Fr chest tube placed in a dependent area (usually the posterior costophrenic recess). If pleural infection is confirmed and all fluid is drained, then the tube is generally left in place until drainage is very low, typically less than 30 to 40 mL/day.

Complicated parapneumonic effusions and empyema are characterized by a procoagulant state within the pleural space, which results in the progressive development of dense layers of fibrin and loculations, as discussed earlier. These complex loculated effusions are unlikely to be adequately drained with simple tube thoracostomy. In an attempt to aid drainage of loculated areas of empyema, instillation of fibrinolytic agents via the chest tube has been proposed as a means of avoiding operation.

Intrapleural instillation of fibrinolytic agents can theoretically dissolve fibrinous clots and adhesions and prevent pleural loculations. The use of fibrinolytic agents is appealing because the most common reason for failure of pleural drainage among patients with an appropriately positioned catheter is occlusion of the catheter by viscous fibrin-rich fluid and/or debris, or partitioning of the pleural space with fibrin bands that loculate pleural fluid and prevent it from reaching the chest tube. Side effects with fibrinolytics are minimal with rare reports of fever and bleeding.³²

Streptokinase, urokinase, and tissue plasminogen activator have all been instilled via chest tube. Streptokinase is usually administered as 250,000 IU in 100 to 200 mL saline daily for up to 7 days. Urokinase is usually administered as 100,000 to 200,000 IU in 100 mL saline daily up to 3 days. Tissue plasminogen activator is administered as 10 to 25 mg twice daily up to 3 days. Drains are typically clamped for several hours following the administration of the fibrinolytic. Tissue plasminogen activator, a recombinant agent, provides fibrinolytic activity without the risk of antigenic-based reactions that can be seen with repeated administration of streptokinase.³³

Tuncozgur and colleagues³⁴ looked at fibrinolytic versus saline instillation via chest tube in 49 patients. They found a significantly lower decortication rate (60% vs. 29%) and shorter duration of hospitalization (14 vs. 21 days) with the addition of intrapleural fibrinolysis as well as a greater volume of chest tube drainage (1.8 liters vs. 0.8 liters). It should be noted, however, that even a 14-day hospital stay is considerably longer than what is expected following an expeditious video-assisted thoracic surgery (VATS) decortication. A single-center randomized placebo-controlled study by Diacon and colleagues³² reported that intrapleural streptokinase resulted in faster resolution of infection, reduced need for surgery (13.6% vs. 45.5%), and improved outcomes in patients with complex parapneumonic effusions and empyema.

Another prospective study by Mithos and colleagues³³ investigated tube thoracostomy versus tube thoracostomy and streptokinase. Tube thoracostomy alone

was successful in 67% of cases. Instillation of streptokinase led to a favorable outcome in 87% and significantly shortened hospital stay, reduced the mortality rate, and reduced the rate of surgical intervention. Davies and colleagues³⁵ compared fibrinolysis versus saline control in the second to fifth hospital day in 24 patients with tube thoracostomy for empyema. These investigators looked at volume of drainage and improvement in chest radiographs. Fibrinolytics caused an increased rate of fluid drainage and greater improvement on chest radiograph. No bleeding complications were seen. Three patients in the control group and none in the fibrinolytic group required surgical drainage.

Bouros and colleagues³¹ compared fibrinolytics with saline control in 31 patients. Fibrinolytic patients had a larger volume of drainage and higher rates of successful chest tube drainage (87% vs. 25%) compared with saline control patients. Two patients treated with fibrinolytic therapy required surgical drainage and 12 patients with saline crossed over to fibrinolytic therapy, with 6 of 12 ultimately requiring surgical drainage.

Tokuda and coworkers³⁶ performed a meta-analysis of all the major placebo controlled studies involving intrapleural fibrinolysis. The meta-analysis showed a trend toward improved survival and a decreased need for surgical interventions. The differences, however, failed to be statistically significant.

In the largest prospective, multicenter, double-blind controlled trial to date, the Multicenter Intrapleural Sepsis Trial (MIST) studied the use of intrapleural streptokinase for the treatment of empyema.³⁷ A total of 454 patients with pleural pus, pH less than 7.20, or positive bacterial culture from the pleural space were randomized to chest tube drainage with streptokinase (250,000 IU twice daily for 3 days) versus chest tube drainage with saline placebo. Primary endpoints of the study were death and need for surgical drainage. The proportion of patients who died or needed surgery at 3 months (primary endpoints) was similar between streptokinase and control (31% vs. 27%). No differences in mortality, rate of surgery, radiographic outcomes, or length of hospital stay were shown. This large study showed that intrapleural streptokinase offered no additional benefit in the treatment of empyema over chest tube drainage alone.

For free-flowing uncomplicated parapneumonic effusions or empyema, tube thoracostomy or percutaneous catheter drainage remains the standard of care. No high-grade evidence from a large-scale randomized controlled study exists to support the administration of fibrinolytic therapy.

Fibrinolytic therapy may be considered in poor surgical candidates who fail chest tube drainage, in patients who require a period of medical stabilization before surgery is performed, and in centers where surgical facilities are limited. Patient factors, local expertise, and surgical availability to a certain extent dictate the initial choice between tube thoracostomy and fibrinolytics or thoracoscopy.

Surgical drainage via thoracoscopy is indicated in patients who fail chest tube drainage, in patients whose lung does not reexpand following either thoracentesis or

tube thoracostomy, or as the initial treatment in patients who, based on chest computed tomography (CT) appearance, are unlikely to be effectively treated with a chest tube. These include patients with very loculated effusions, patients with thick pus, or with a thick pleural rind on CT scan. Loculations can be broken down, thick pleural fluid and debris completely evacuated, the pleural space can be extensively lavaged, and chest tubes can be carefully placed. Several small retrospective and non-blinded prospective studies suggest that thoracoscopy is superior to tube thoracostomy with fibrinolytics, with the need for thoracotomy halved.³⁸⁻⁴⁰

In the only prospective randomized controlled trial of fibrinolytic therapy versus thoracoscopy for empyema, Wait and coworkers⁴¹ randomly assigned 20 patients with complicated multiloculated parapneumonic empyema to streptokinase (250,000 IU daily for 3 days) via tube thoracostomy or immediate thoracoscopic drainage. Thoracoscopy had a higher treatment success rate (91% vs. 44%), lower duration of chest tube drainage (5.8 vs. 9.8 days), and a shorter hospital stay (8.7 vs. 12.8 days). This study supports the preferred approach of primary thoracoscopic drainage in patients presenting with loculated collections, provided that they are suitable candidates for surgical intervention.

Often in the chronic organizing phase of empyema, a thick fibrous peel builds up on the visceral pleura that restricts lung mechanics and prevents lung reexpansion, even after fluid drainage. The procedure allows for excision of all the fibrous tissue from the pleura to permit lung reexpansion.⁴² Decortication relies on lung elasticity to fill the cavity. Failure of reexpansion of the lung in the acute phase may result when there is densely consolidated lung that does not fully reexpand after drainage of fluid, even with decortication. Lung constriction after empyema can reduce lung perfusion by 20% to 25% on the involved side. The pulmonary function of patients who undergo decortication can increase significantly. Decortication can improve lung perfusion and improve vital capacity from 62% up to 80% and the forced expiratory volume after 1 second (FEV₁) from 50% to 69%. Nonetheless, decortication remains a procedure with significant morbidity and a reported mortality rate of up to 10%.⁴² Some investigators have suggested that pleural thickening may resolve over time and recommend deferring decortication for up to 6 months, but this opinion is in the minority.⁴³ In patients suffering from overwhelming sepsis, pleural drainage by tube thoracostomy or expeditious VATS is the immediate goal. Decortication may then be performed at a later date when the patient is stable. Delayed decortication is advised if there remains significant restriction of the affected lung and if the patient is a good operative risk.

For patients in whom sepsis cannot be controlled acutely with thoracoscopic drainage and in whom decortication is not appropriate, window thoracostomy may be performed. Open thoracostomy may be the procedure of choice if there is a permanent supply of causative organisms as a result of a bronchopleural fistula or if there is a space issue such as in a postpneumectomy empyema (Figs. 28-5 to 28-8).

SPECIAL CONSIDERATIONS: POSTPNEUMONECTOMY EMPYEMA AND BRONCHOPLEURAL FISTULA

Incidence

Empyema is uncommon following pulmonary resection, occurring in only 2% to 16% of patients.⁴⁴⁻⁴⁶ Most (80% to 90%) postpneumonectomy empyemas are the result of a bronchopleural fistula (BPF) and carry a mortality rate of 5% to 35%.^{47,48} BPFs have been noted to occur in 2% to 10% of pneumonectomies.⁴⁴ Deschamps et al⁴⁹ reviewed 713 patients who underwent pneumonectomy at the Mayo Clinic between 1985 and 1998. Ten percent of the pneumonectomies were performed for benign

FIGURE 28-8 ■ Cross-sectional view of the drained empyema cavity and the completed modified Eloesser flap, with tongue flap sewn to the base of the empyema cavity.

disease. The incidence of postpneumonectomy empyema was 7.5% and the incidence of postpneumonectomy BPF was 4.5%. Variables associated with an increased incidence of postpneumonectomy empyema were benign disease, lower preoperative FEV₁, lower preoperative diffusion of carbon dioxide in the lung (DLCO), lower preoperative serum hemoglobin, right pneumonectomy, stump reinforcement, completion pneumonectomy,

timing of chest tube removal, and blood transfusion. Variables associated with the occurrence of BPF were benign disease, lower preoperative FEV₁ and DLCO, right pneumonectomy, bronchial stump reinforcement, timing of chest tube removal, increased intravenous fluid in the first 12 hours, and overall amount of blood transfused.

It is generally accepted that bronchial stump reinforcement is protective against BPF. The unexpected findings in this study may be related to the surgeon's choice to use bronchial stump reinforcement for those patients believed to be at highest risk for stump breakdown. Bronchial stump closure with staples had a protective effect against BPF compared with suture closure. Factors not affecting the incidence of PPE or BPF were gender, age, smoking history, associated cardiovascular disease, corticosteroid use, chronic renal failure, diabetes mellitus, hematologic disease, cirrhosis, nonpulmonary malignancy, body mass index, weight loss, stage, preoperative chemotherapy or radiation therapy, preoperative percentage of predicted total lung capacity and residual volume, PaO₂, and PaCO₂, extended resection, and duration of postoperative mechanical ventilation.

The signs and symptoms of postpneumonectomy empyema initially consist of low-grade fever, malaise, and leukocytosis. The appearance of air in the pleural fluid after pneumonectomy is nondiagnostic; however, a drop in the air-fluid level is strongly suggestive of a BPF even in the absence of other symptoms. Computed tomography can be helpful in demonstrating the size and location of loculated air-fluid pockets. It may also show reversal of the normal concavity of the mediastinal margin with increased thickening of the residual parietal pleura.^{50,51} Air in continuity with the bronchial stump may raise suspicion of a BPF but is not diagnostic. Bronchoscopy should be performed if the diagnosis of empyema is suspected after pulmonary resection. The bronchial stump should be thoroughly inspected for a small BPF. Similarly, the contralateral airway should be inspected and sputum collected for cultures. *Staphylococcus aureus* and *Pseudomonas aeruginosa* are the organisms most frequently involved.⁴⁹ In patients with suspected early empyema who have no evidence of a fistula, systemic antibiotics and observation may be the most appropriate management option. In cases of confirmed postpneumonectomy empyema, however, treatment follows the well-established rules of managing any abscess.⁴⁹ These management rules include adequate pleural drainage, appropriate parenteral antibiotics, removal of necrotic tissue, and obliteration of residual space. Obliteration of the empyema space can be accomplished by transposition of viable tissue such as omentum or skeletal muscle; this can be performed as a primary procedure to manage an empyema space or as a staged procedure some months after an open thoracostomy.

Treatment

When the patient presents acutely with clinical features of a BPF, contralateral pneumonitis, and respiratory distress, initial management begins with emergency chest tube drainage of the cavity to control infection and stop

contralateral spillage. The patient should be positioned in the lateral decubitus position with the pneumonectomy side down until adequate drainage of the pleural space is achieved. Simultaneously, respiratory support is provided as clinically needed. When a large BPF is present and mechanical ventilation is required, a double-lumen endotracheal tube or a straight, long single-lumen tube is used to ventilate the remaining lung and bypass the fistula. The ventilation of these patients can be extremely challenging. If the fistula occurs in the perioperative period (i.e., within the first month or so), repeat thoracotomy and attempted closure of the stump with muscle flap reinforcement and drainage of the pleural space are recommended. After this time, scarring and granulation tissue prevent the precise placement of bronchial stump sutures. Other treatment options include thoracoplasty,⁵²⁻⁵⁴ open pleural drainage,⁵⁵⁻⁵⁷ and transsternal, transpericardial closure of the fistula.⁵⁸⁻⁶⁰ If bronchoscopy reveals a long main bronchus stump (i.e., >1 cm), then transsternal, transpericardial closure with a thoracoabdominal (TA) stapler may be a good option.

Rarely, carinal resections have been used for treatment of a pneumonectomy stump BPF.⁶¹ Clagett and Geraci in 1963⁶² showed that post-pneumonectomy empyema could be successfully treated by open pleural drainage, frequent wet-to-dry dressing changes, and, when the thorax was clean, secondary chest wall closure with obliteration of the pleural cavity with an antibiotic solution. Failure was most often due to a persistent or recurrent fistula.⁶⁰ Because of this, the original Clagett technique is modified when a BPF is present to include transposition of a well-vascularized muscle to cover the stump at the time of open drainage to prevent further ischemia and necrosis.⁶³ Our preference is intrathoracic transposition of extrathoracic skeletal muscle.⁶³⁻⁶⁷ Usually, the serratus anterior muscle is intact despite a previous thoracotomy. Other available muscles include the pectoralis major, the cephalic portion of the previously transected latissimus dorsi, and the rectus abdominis. The advantages of using these muscles include adequate bulk, an axial blood supply, and the muscle's availability in the same visceral cavity. Transposition of the latissimus dorsi and pectoralis major muscles results in minimal cosmetic or functional abnormality; transposition of the serratus anterior muscle, however, may result in scapular winging.

CONCLUSIONS

Patients with pneumonia and associated pleural effusion should initially be evaluated with thoracentesis. Presence of loculations or pleural fluid analysis showing bacteria on Gram stain or culture, low glucose or low pH, and frank pus are all indications for immediate drainage. Nonloculated parapneumonic effusion and empyema may be adequately treated with tube thoracoscopy, but loculated effusions, or those inadequately drained with a chest tube, are best treated with thoracoscopic drainage. The fundamental principles of therapy are to remove infection and allow for lung reexpansion to obliterate dead space. If visceral scarring results in lung entrapment, then decortication is required. With recent advances in

VATS technology and skills, most decortications can be performed using minimally invasive techniques. Open decortication is usually reserved for patients with severe scarring after remote pleural empyema. If a significant pleural space exists and decortication is not possible, then the options are thoracoplasty, muscle flap transposition, or open window drainage.

CHAPTER OUTLINE

DEFINITION

CLASSIFICATION AND CAUSE

ANATOMIC CONSIDERATIONS

PATHOPHYSIOLOGY

SYMPTOMS AND DIAGNOSIS

PRINCIPLES OF MANAGEMENT

Chylothorax after Pulmonary Resection

Chylothorax after Esophagectomy

CONCLUSION

DEFINITION

Chylothorax is the collection of an excessive amount of chyle in the pleural space. The continued loss of chyle, which can add up to 2 to 3 liters a day after a thoracic duct injury,¹ leads to significant depletion of fats (up to 70% of dietary intake), proteins, and T lymphocytes.² As a consequence, marked disturbances in the immunologic and nutritional profile are the rule in these patients along with a mass effect created by dislocation of intrathoracic structures by the enlarging fluid collection. Indeed, the flow rate of chyle within the thoracic duct can be as high as 110 mL/hr.¹ If left untreated, chylothorax may yield an overall 50% mortality rate.³

CLASSIFICATION AND CAUSE

The term *traumatic* is often used to include both iatrogenic and postinjury chylothoraces,² which usually represent the most common causes of significant chyle accumulation in the chest. Neoplastic causes can account to up to 20% of chylothoraces.² In a recent report from the Mayo Clinic, the cause was surgery or trauma in 50% of the patients, medical conditions in 44%, and unknown in 6%.⁴ This unusual distribution, compared to the commonly reported series,⁵ was explained by the high volume of surgical cases being performed each year at that institution.

In the pediatric group, congenital chylothorax manifests itself early after birth possibly as a result of a combination of thoracic duct malformation and sudden elevation of venous pressure.⁶ Neonatal chylothorax has been reported in conjunction with several syndromes, such as Noonan and Down.^{2,6} In addition, the incidence of chylothorax after cardiothoracic procedures in children is reported to be as high as 3.8%.⁷ The detection of a pleural effusion in this age group should immediately

raise the suspicion of chylothorax.⁶ Tuberculosis with significant mediastinal adenopathy may still be responsible for “spontaneous” bilateral chylothoraces in children because of the obstruction to centripetal flow.⁸

Excessive chyle collection in the pleural space may occur in association with benign and malignant tumors. Reportedly, almost 50% of the patients with chylothorax have cancer. Of these, 70% have lymphoma.⁵ Conversely, chylothorax was reported in 10% of the patients with lymphangioliomyomatosis (LAM) treated at the Mayo Clinic over a 24-year period.⁹

Intraoperative injuries may ensue from surgical procedures conducted in the proximity of the thoracic duct anatomic course.^{2,10,11} Even minor maneuvers such as raising a pleural flap over the thoracic aorta or dividing the inferior pulmonary ligament can cause this complication.¹² In 1999, the Mayo Clinic reported that out of 11,315 general thoracic surgical procedures, 47 patients (0.42%) had postoperative chylothorax.¹

Chylothorax can complicate the postoperative course of 1% of esophagectomy patients,¹³ requiring surgical reexploration in almost 90% of the cases.³ Conversely, despite chylothorax occurring in less than 1% of the patients subjected to pulmonary resection, only 38% undergo reoperation for final treatment.¹ A detailed list of possible causes of chylothorax was reported by De Meester¹⁴ in a previous edition of this textbook and later modified by Nair.²

ANATOMIC CONSIDERATIONS

A certain variability in the distribution of the thoracic duct and its tributaries represents the rule rather than an exception. At some point in the embryogenesis, the thoracic duct itself is a bilateral structure¹⁵ and can triplicate in up to 40% of the population.¹⁵ The single thoracic duct anatomy is found in approximately 65% of the individuals. Chylothorax can result from leak of lymph from

major collectors—the most sizeable being the thoracic duct—or from multiple lymphatic channels, which define a network of tributaries consistently demonstrated by several anatomic studies.¹¹

The centripetal flow toward the left subclavian vein is regulated by three factors¹⁷: (1) the vis a tergo created by the continuous enteral absorption of chyle constituents, which pushes the chyle from the cisterna chyli to the left subclavian vein; (2) the aspiration effect given by the negative effect of the intrathoracic pressure facilitating the cephalad flow; and (3) lymphatic vessel contractions, generated by smooth musculature, aiming at emptying the duct into the subclavian vein.

PATHOPHYSIOLOGY

A chylothorax can result from a chyle leak (direct injury or obstruction of the major lymphatic vessel), generalized oozing, or transdiaphragmatic flow from chylous ascites.⁹ The distinction between idiopathic (sometimes called spontaneous) and secondary causes of chylothorax depend on the presence of an identified etiology. Secondary causes include neoplastic and inflammatory conditions because chylothorax may ensue from the obstruction to centripetal flow or increased flow rate with extreme dilation of lymphatic vessels leading to extravasation of lymph in a space that changes from virtual to actual despite the presence of an expanded lung. As a consequence, lymphatic vessels are thought to preserve, at the beginning, their structural integrity at the expense of an increased permeability into the pleural space.^{2,9} Constrictive pericarditis, superior vena cava obstruction, and mediastinal fibrosis resulting from cancer treatment can generate chylothorax according to this pathophysiologic model.⁵ In this setting, patients with liver cirrhosis can develop spontaneous chylothorax as a result of a twofold or threefold increase in diameter of the thoracic duct from an unusual backflow and pressure in the thoracic duct.¹⁶ Another factor implied in the onset of chylothorax is valve competency in the lymphatic vessels as demonstrated by the rarity of such complication following pulmonary resection and extensive mediastinal nodal dissection. Valve insufficiency–induced backflow from the thoracic duct into the areas of nodal dissection and injury of the lymphatic network may explain the chylous effusion¹¹ after pulmonary resections with concurrent nodal dissection.

From a clinical standpoint, chylothorax resulting from pleural carcinomatosis or from tubercular involvement may denote a gradual onset and development. This observation can be also explained by progressive lung trapping caused by the visceral pleura thickened by the persistent chemical irritation by chyle components.¹² In time, fibrotic visceral pleura may impose a restrictive physiology on the affected lung by significantly reducing its compliance. This scenario is more often the case with the so-called pseudochylothorax (see later).

Induced or secondary causes of chylothorax include traumatic and iatrogenic causes, which have in common the interruption of the vessel caused by direct injury, inadvertent division, or blunt trauma to the thoracic duct

or its tributaries. Rupture of the thoracic duct may also occur following sudden hyperextension of the spine (seat belt injury),¹⁸ vertebral fractures or dislocation, or after protracted and vigorous vomiting or coughing.⁶

SYMPTOMS AND DIAGNOSIS

Biochemically, chyle is usually characterized by a content of triglycerides in the pleural fluid greater than the one detected in the plasma (>110 mg/dL¹), a cholesterol/triglycerides ratio less than 1, and, the presence of chylomicrons.^{2,6,19–21} A detailed description of the chemical components of chyle is already available in the surgical literature.^{1,6} A differential diagnosis with pseudochylothorax sometimes has to be made.² Pseudochylothorax refers to those chronic effusions that may resemble chylothorax but do not have its biochemical composition.² The pleural effusions in patients with tuberculosis or rheumatoid arthritis may have these features (i.e., yellowish or milky color, sterile, high cholesterol levels).

One interesting observation is that chyle does not contain fibrinogen, which could seal a small leak.³ Chyle is bacteriostatic and can be a chemical irritant for the pleural surfaces,¹² even though this finding is disputed.^{2,17} In addition, chylothorax can affect the bioavailability of drugs like amiodarone, digoxin, and, cyclosporine.²

The acute onset of a significant chyle leak may be characterized by dyspnea and cough associated with a sense of pressure in the chest.² Hemodynamic disturbance is also common with high-flow chylous fistulas.² Conversely, severe malnourishment and cachexia may ensue as a result of persistent chylothorax.² Symptoms related to chyle accumulation were described in a report by the Mayo Clinic.⁴ Over a 21-year observation period, 203 patients developed chylothorax (male-female ratio, 1.21; median age, 54 years). Of these patients, 57% presented with dyspnea, whereas 37% were asymptomatic. More than 7 weeks elapsed from symptom development to diagnosis.⁴

A milky pleural effusion accumulating at a rate of more than 400 to 700 mL per day is suggestive of chylothorax.¹² An empty pleural space after pneumonectomy may accommodate a greater chyle flow.¹² The administration of a high-fat meal 3 hours before surgery, with or without dye, or the subcutaneous injection of dye 1 hour before surgical exploration can facilitate the identification of the site of leakage when the decision for surgery to ligate the duct is made.¹²

Some authors rely on the findings of pedal lymphography to define further management.^{16,22} Indeed, the discontinuation of chyle leak after lymphography represents a distinct therapeutic possibility¹⁶ because of the sclerosing effect of the iodine contrast medium. Controversies exist whether to proceed to lymphography only in candidates for surgical reexploration or to routinely proceed in all patients developing chylothorax after pulmonary resection.²³ However, the reported success rate in minimizing the need for reoperation through the adoption of a rigorous management protocol, including lymphography, seems to support the latter option.²²

Nevertheless, the lymphographic finding of a leak from small tributaries may predict the success of conservative management.¹⁶

PRINCIPLES OF MANAGEMENT
(Table 29-1)

Three approaches to managing chylothorax are:

- 1. Conservative (nonsurgical)
- 2. Surgical, aimed at identifying and isolating the lymphatic duct causing the leak so that it can be closed
- 3. Surgical, aimed at obliterating the space otherwise to be filled by chyle

Conservative management represents a mainstay of treatment of postoperative chylothorax developing in children following cardiothoracic interventions.⁷ The principles of conservative treatment include (1) nothing by mouth (NPO), (2) medium-chain triglyceride diet, or (3) parenteral nutrition.¹²

In adults, it has been suggested that the detection of recurrent chylothorax greater than 1 liter/day after 1 week or between 0.1 and 1 liter chyle loss during the first two weeks¹⁶ is evidence of failure of conservative management. Others¹² suggest opting for a surgical intervention if the leak is greater than 1 liter/day for 5 days, if the chylothorax does not subside after 2 weeks, or if there is severe nutritional or metabolic imbalance. Advocates of early surgical intervention following esophagectomy support the idea of reintervention if the leak is consistently greater than 2 liters during 2 consecutive days.³ An interesting perspective for chylothorax treatment has been outlined by Cope, who suggested percutaneously injecting a sclerosing agent into the cisterna chyli.²⁴

Surgical intervention or reintervention can be performed via an open or a video-assisted thoracic surgery

(VATS)/robotic approach.²⁵ The increasingly frequent resort to safe minimally invasive techniques to achieve control of the thoracic duct may change the balance between conservative and operative approaches. Indeed, the therapeutic possibilities revolve around the identification of the leak, closure of the fistula, and obliteration of the pleural space, especially if the chylothorax complicates an esophagectomy (see Table 29-1). On principle, the side of the identified leak should be preferentially approached and surgically treated.³ In the event of a bilateral chylothorax, the right side should be preferentially entered to ligate the supradiaphragmatic thoracic duct. If the duct cannot be isolated, mass ligation of the fibrotic area around the duct should be performed.¹² The treatment options suggested in the literature are listed in Table 29-1.

Chylothorax after Pulmonary Resection

Despite the fact that a well-expanded residual lung after lobectomy and postpneumonectomy chylothorax have similar etiologies and pathophysiologies, the former usually responds better to a conservative approach.²¹ In the latter, sudden accumulation of chyle in the empty hemithorax can cause a contralateral shift of the mediastinum with the attendant cardiorespiratory functional impairment. This rare clinical scenario, reported in almost half of the pneumonectomy patients who develop chylothorax,²⁶ mandates a more aggressive protocol to ensure early ligation of the thoracic duct—within 3 to 5 days of onset if the chyle loss is greater than 400 mL after an observation period lasting two consecutive 8-hour shifts.²¹

Reportedly, chylothorax occurs more frequently on the right side, possibly because of a more radical mediastinal nodal dissection following resection for bronchial carcinoma.¹⁶

Chylothorax after Esophagectomy

Patients undergoing esophagectomy are often older adults with significant cardiorespiratory comorbidities and malnourishment.¹³ In addition, multiple operative fields are necessary to complete the esophageal resection and restore the gastrointestinal continuity. The resort to VATS has reduced the impact of this operation on patients' overall condition. In a series of 1787 patients operated on during an 18-year period, 26% underwent a transhiatal esophagectomy as a result of their substantial cardiorespiratory comorbidities.¹³ However, no significant difference in the prevalence of chylothorax was noted between trans-thoracic and transhiatal approaches.¹³ In a Mayo Clinic series, the incidence of this complication following esophagectomy was reported to be 2.9%.¹ Investigators renowned for their long-standing experience with transhiatal esophagectomy (reaching almost 2000 patients subjected to this procedure) have reported an incidence of chylothorax of 1.5%, favorably comparing with the 2% to 4% range reported in the literature.²¹

Early reoperation with mass ligation of the thoracic duct is advocated to limit the immunologic and nutritional imbalances that can heavily affect the postoperative course of these patients.¹³ The mortality rates for

reoperation reach 16% compared with more than 80% after conservative treatment,³ making an early surgery option to control chylothorax a preferable option. However, the prophylactic ligation of the immediately supradiaphragmatic azygos vein along with the thoracic duct during esophagectomy has been recommended to drastically reduce the incidence of chylothorax.^{2,13}

CONCLUSION

Among different types of chylothoraces, postoperative chylothorax represents a serious challenge, especially when esophagectomy is performed after induction therapy (Table 29-2). Current conservative treatment, in addition to time-honored strategies, tends to include diagnostic lymphangiography³⁷ and midodrine, an α -adrenergic drug available for oral administration.³⁸ Conservative treatment, combined with surgical treatment when necessary, leads to resolution in most patients.

Treatment

MALIGNANT PLEURAL EFFUSIONS

Pleural effusions are common clinical problems occurring in more than 1 million patients each year.¹ In some settings, up to 22% of these effusions are caused by malignant disease and more than 100,000 malignant effusions require treatment annually.² Affected patients with advanced neoplastic diseases experience considerable morbidity as a result of these pleural fluid collections.

Physiology

Pleural effusion results from a derangement in the normal physiology such that there is increased production of pleural fluid or a change of its composition with or without a reduction in the absorption of the fluid. This may be to the result of primary or secondary tumors of the pleura with seeding of the intrapleural space and lymphatic obstruction. Free-floating tumor cells block absorption of fluid and produce vasoactive substances that in turn increase the production and block the absorption of intrapleural protein and fluid.^{3,4}

Demographics

In adults, 95% of neoplastic pleural effusions arise from a metastatic source, with lung and breast carcinoma accounting for 75% of all cases.⁵ Other common

causes are lymphoma, gastric cancer, and ovarian cancer. Approximately half of patients with breast cancer develop a pleural effusion within their lifetime, as compared with one fourth of patients with lung cancer and one third of patients with lymphoma.

Most pediatric effusions, on the other hand, are benign. If malignant, lymphomas or leukemias account for half with the remainder a mix of tumors such as neuroblastoma, Wilms tumor, and germ cell neoplasms.⁶

Adenocarcinomas whose primary is unknown constitute a distinct entity in patients in whom the source of the pleural malignancy is never found. They are associated with exposure to environmental tobacco smoke.⁷

Evaluation

Historical and Physical Findings

Patients with malignant pleural effusions are typically symptomatic and complain of dyspnea, cough, or chest pain. The discomfort often is independent of respiration but is aggravated by activity. With invasive pleural metastases, the affected nerve roots may radiate pain. Like pericardial effusions, rapid fluid accumulation amplifies the symptoms. For at least 10% of patients, the dyspnea is multifactorial and does not improve after drainage. Physical findings indicating pleural effusion are decreased tactile fremitus and dullness to percussion

on examination of the posterior chest, accompanied by decreased breath sounds. As the effusion increases in size, there may be hyperresonance on percussion immediately above the fluid level because of compression and overdistention of the lung. Bronchial breath sounds may be prominent. As effusions become massive, tracheal deviations from mediastinal shifts are detectable. Malignant pleural effusions rarely cause hemodynamic compromise from tension hydrothorax.

Imaging

Early evidence of pleural effusion by chest radiograph is costodiaphragmatic sulcus blunting caused by as little as 125 to 250 mL of fluid, depending on the quality of the film (Fig. 30-1). Occasionally, a spurlike shadow projects into the fissure. Massive effusions are uncommon; however, when they occur, they are more likely malignant. In patients in whom the finding is uncertain, a decubitus film might show shifting of the fluid. Effusions wider than 10 mm by decubitus film often are tapped successfully.⁸

There are specific computed tomography (CT) criteria for pleural effusions. In general, loculation, pleural thickening, pleural nodules, and extrapleural fat of increased density are present only in exudative effusions. Multiple pleural nodules and nodular pleural thickening are generally limited to effusions of malignant origin (Fig. 30-2). Pleural thickening greater than 1 cm also is a reliable criterion.⁹ Magnetic resonance imaging (MRI) has limited use, but it may be slightly more useful for certain pleural tumors such as lipoma; it also can be helpful in determining the extent of invasion for mesothelioma.¹⁰ Thoracic ultrasound shows the optimal site for diagnostic thoracentesis of a small pleural effusion. It also helps in the selection of ideal entry points for thoroscopes or pleural biopsy instruments by avoiding adhesions.¹¹ In addition, ultrasound has moderate accuracy in predicting the malignant nature of the effusion.¹²

FIGURE 30-1 ■ Chest roentgenogram showing large right pleural effusion (outlined by arrows).

Positron emission tomography (PET)–CT scans may detect early pleural metastases before other imaging tests. If nuclear imaging reveals pleural activity and pleural fluid is scant, diagnostic thoracoscopy is necessary to exclude pleural disease provided this staging is relevant. Limited data suggest a high degree of diagnostic accuracy in differentiating benign from malignant pleural effusions.¹³ Figure 30-3 shows an image of a PET scan demonstrating a malignant pleural effusion.

Diagnostic Procedures

The diagnosis of pleural effusion is confirmed by thoracentesis. Withdrawing only a small portion of pleural fluid is indicated occasionally when full lung reexpansion is unlikely or as a prelude to a definitive drainage procedure. It is usually preferable to attempt drainage of as much pleural fluid as possible (Fig. 30-4).

FIGURE 30-2 ■ **A**, CT images of a malignant pleural effusion. **B**, Chest CT from a patient with breast carcinoma, with recurrent basilar left pleural effusion after partially successful chemical sclerosis. The image shows partial pleurodesis, pleural thickening, and a pleural nodule (arrow) at the level of the mid thorax. E, Effusion; L, prevascular lymphadenopathy.

Several commercial kits facilitate drainage by allowing insertion of soft catheters with side holes to completely evacuate the fluid. The catheters can be readjusted during drainage in case the lung temporarily occludes the holes. Needles with retractable blunt obturators (e.g., Turkel needle) also prevent lung injury during pleural entry. Physical examination can guide a pleural tap. On the other hand, ultrasound or other imaging can optimize needle or chest tube placement for effusion drainage in more complex situations (Fig. 30-5). This is particularly useful for a small effusion or pleural disease of long

duration complicated by lung consolidation or pleural loculation. Although marking of the area of “deepest” fluid is useful, it is important to perform the thoracentesis with the patient in the same position as during the imaging. Attempts to completely aspirate chronic effusions should be undertaken carefully. High vacuum applied to the pleural space, by either syringe aspiration or vacuum bottle, is sufficient to rupture alveoli and cause a complicated hydropneumothorax.

Standard Chemistry and Cell Counts

Practically all malignant pleural effusions are exudates. Laboratory criteria to establish exudative effusions are based on absolute values or ratios to systemic parameters. One of the most useful sets of criteria used to classify effusions as exudative was described by Light: pleural fluid/serum total protein ratio greater than 0.5, pleural fluid/serum lactate dehydrogenase (LDH) ratio greater than 0.6, and pleural fluid LDH greater than 200 U/liter (greater than two thirds of the laboratories' upper limit of normal for serum).^{1,14}

Low glucose (<60 mg/dL) and low pH (<7.20) levels are common in malignant pleural effusions.¹⁵ This is attributed to glucose usage and acid production by the malignant cells, leukocytes within the pleural fluid, and also increased pleural membrane metabolism. Investigators have alternatively implicated abnormal pleural membrane transport of glucose, carbon dioxide, and hydrogen ion.¹⁶ Pleural fluid amylase is elevated in approximately 10% patients with malignant pleural effusions, even without pancreas gland disease.¹⁷ In fact, the most common cause of an amylase-rich pleural effusion is neoplasm.¹⁸ The cell count can also indicate malignancy. For some investigators, bloody fluid is the strongest positive predictor of malignant effusion. Fluid viscosity has also been studied as a diagnostic test.¹⁹

FIGURE 30-3 ■ PET scan demonstrating uptake on the side of the chest with the malignant pleural effusion.

FIGURE 30-4 ■ **A**, Common patient position for insertion of a thoracentesis needle or catheter. Posterior approach allows access to the most dependent (posterior pleural) sulcus to allow maximal drainage of nonloculated fluid. **B**, Lateral patient positioning for thoracentesis or chest tube placement is also useful for effusions with large lateral collections of fluid. The patient's arm is abducted and flexed over his head to facilitate access to the lateral chest.

Immunocytochemistry and Special Chemistry

Many investigators focused their explorations on staining patterns of cells obtained from pleural fluid to confirm

FIGURE 30-5 ■ Ultrasound of right lateral chest to facilitate safe pleural access. E, Effusion; H, hepatic lobe; L, lung.

malignancy, and, if present, correctly classify its origin. Unfortunately, markers are not yet sufficiently sensitive and specific, but they generally show twice the positivity of cytology alone (80% versus 40%).²⁰ These tests usually are used after standard cytologic screening and in combination with cytogenetic and other miscellaneous tests to establish a diagnosis. A more complete list is displayed in [Table 30-1](#).

Some of these markers, such as p53, predict a worse prognosis for malignant effusions that are p53-negative.²¹ Another marker, Ki-67, is associated with a worse prognosis when its labeling index is low.²²

Vascular endothelial growth factor (VEGF) has been found to be a useful discriminator for malignant effusions.²³ Other special chemistry values, displayed in [Table 30-2](#), are occasionally useful to categorize malignancy. The sensitivities and specificities vary by specific cell types.

In the past few years, epigenetic biomarkers for cancer have been studied. These include markers to differentiate benign from malignant pleural effusions.^{24,25} These markers often have the advantage of easier sample processing and, if validated, may impact the field significantly.

Cytogenetics

DNA testing by flow cytometry or chromosome analysis predicts the likelihood of malignancy. The evidence of a marker chromosome, aneuploidy, or a hyperdiploid state suggests malignancy. Aneuploid samples (by flow cytometry) yield predictive values as high as 96%.²⁶ No aneuploidy was found in benign reactive effusions in one series.²⁷ Telomerase activity occurs in 92% of malignant effusions and in only 6% of benign effusions (with a specificity of 94.2%).²⁸

Pleural Cytology and Biopsy

Cytologic evaluations with standard staining (Papanicolaou smears) can sometimes confirm malignant pleural effusions. In very unusual cases (0.5%), the results are falsely positive.²⁹ In cytologic specimen reviews, lung adenocarcinoma is the most frequent diagnosis. Breast cancer effusion specimens have a higher cytology diagnostic yield (approximately 78%) than lung or other tissue primaries.³⁰ The sensitivity of pleural fluid cytology frequently is greater than undirected pleural biopsy.

When standard pleural effusion cytology is nondiagnostic, pleural needle biopsy occasionally provides some additional useful diagnostic information (48% in one series).³¹ However, whether pleural biopsy adds much over fluid cytologic evaluation in cases of suspected malignancy is controversial. In another series, only 7% of the cases had a diagnosis made by use of pleural biopsy when the cytology result was negative.³² This can be enhanced by the use of ultrasound to perform a directed biopsy.³³ For difficult cases, cytology combined with needle biopsy results are inferior to those obtained by video-assisted thoracic surgery (VATS) (41% versus 97%).³⁴ In several series, a typical yield of undirected pleural needle biopsy of 50% to 60% was far inferior to biopsies obtained by VATS. Use of a directed VATS

approach in these cases achieves greater than 90% success.³⁵ With idiopathic effusions (20% in some series), uncertainty is reduced to 4% using thoracoscopy. The complication rate from thoracoscopic biopsy is low, with mortality rates less than 1% and complication rates less than 10%.³⁶ Figure 30-6 shows thoracoscopy images that confirmed pleural malignancy.

A technique variation that might shift results of “blind” biopsy toward those by directed means is the use of a pleural brush to increase the cytologic yield. In one series, this technique was positive in 90% of the cases, as opposed to 67% with the routine cytologic aspirate and 58% with biopsy.³⁷ Thoracotomy to perform pleural biopsy is unusual given successful directed methods such as VATS.

When patients remain without a definitive diagnosis following VATS or thoracotomy, approximately one third will demonstrate a cause (typically lymphoma or mesothelioma) months to years later.³⁸ For patients with massive malignant effusions for which the cause is unknown, fiberoptic bronchoscopy may establish lung cancer. When effusions are mild to moderate and without associated symptoms, the chance of finding a neoplasm is not great enough to warrant bronchoscopy.

In summary, clinical information, conventional cytology results, immunocytochemistry, flow cytometry, and special chemistry test results must be integrated to yield the most accurate diagnosis.

Treatment

The optimal treatment for malignant pleural effusion is controversial. Multiple technologies exist that control malignant pleural effusions successfully. The best selection for a patient is guided by factors such as the individual's frailty and the prognosis of the primary malignancy. The need for additional pleural tissue or directed biopsy, as well as concomitant diagnostic or therapeutic procedures requiring general anesthesia, also guides the choice and timing of pleural interventions.

The anatomic state of the affected thorax is important. For example, a pleural effusion of relatively rapid onset typically yields full expansion of the lung and pleural coaptation after the effusion is evacuated. On the other hand, malignant disease of long duration can prevent full lung expansion because of visceral pleural restriction, endobronchial obstruction, parenchymal fibrosis, or replacement by tumor. To help with planning, good diagnostic imaging is important.

Treatment options can be classified into those that rely on drainage alone or those that also obliterate the pleural space. Because an inflammatory response is associated with most pleural effusions, persistent and complete pleural drainage may also achieve pleural fusion. Recent evidence shows cytokine activation from repetitive pleural draining that supports this view.³⁹ Although pleural malignancy traditionally means surgical incurability, some investigational multidisciplinary methods include operations for selected cases designed to improve the chance for cure.⁴⁰

A chest radiograph after pleurodesis commonly shows multiloculated fluid collections suggestive of empyema. This finding probably represents regions of rapid pleural

FIGURE 30-6 ■ **A**, Lung carcinoma. Parietal and visceral pleural implants with residual effusion are displayed. **B**, Malignant mesothelioma with the “grape cluster” pattern characteristic of pleural tumors. *E*, Effusion (residual); *L*, lung; *P*, parietal pleura.

adhesion formation with intervening accumulations of inflammatory fluid. This is probably an acceptable variation of treatment effect rather than a nonuniform distribution of sclerosing agent.

This imaging appearance generally resolves by 1 to 3 weeks; however, to avoid this phenomenon, some physicians wait for effusion drainage rates to decrease before instilling pleurodesis agents. It is not clear whether this practice is necessary. Long delays before pleurodesis may simply reduce the thoracic cavity area to which the instilled agent is exposed when significant pleural adhesions have already occurred in regions remote to the drainage catheter. Occasionally, significant pleural thickening or even fibrothoraxes occur as long-term sequelae of pleurodesis. The use of thoracic ultrasound (see Fig. 30-5) can guide the optimal drainage site for small pleural effusions or the optimal point of entry of a thoracoscope to avoid adhesions.

Drainage-Based Methods of Malignant Effusion Control

Serial thoracenteses appropriately control malignant pleural effusions for some patients. This option is not effective for durable effusion control but provides temporary symptomatic relief in cases with extremely poor prognoses. Thoracentesis is also ideal when alternate therapy should cause a major reduction in the patient's

effusion. For example, a lymphoma-related effusion may resolve with chemotherapy.

Occasionally, thoracentesis creates a hydropneumothorax because of poor compliance or entrapment of the ipsilateral lung. If the pneumothorax and dyspnea symptoms remain stable and noncompelling, tube thoracostomy should be avoided, because pleural coaptation and effective ventilation from that lung are unlikely. Fluid will replace the air space over time. Lung entrapment can probably be predicted by measurement of pleural pressure swings.⁴¹

Small Catheter Drainage. Implantation of a long-term pleural catheter or placement of a percutaneous medium-durability pleural catheter for continuous or intermittent drainage is better than serial percutaneous aspirations.⁴² The pleural catheters have the advantage of obtaining near complete removal of the pleural fluid in the same way that a tube thoracostomy evacuates the pleural space. Needle aspiration rarely evacuates the fluid completely and rarely maintains the lung expansion long enough for a spontaneous pleurodesis to occur. Even without introduction of any pleural sclerosing agents, pleurodesis occurs simply by maintaining pleural apposition in a select group of patients probably from the underlying inflammation and invasive effects of the neoplasms.⁴³

Using a small silicone catheter (Fig. 30-7) with a valve that allows drainage only when connected to a closed

FIGURE 30-7 ■ PleurX catheter. **A**, Patient connects the PleurX catheter to a bottle for self-drainage. **B**, Close-up of the catheter. Note the one-way valve mechanism (white arrow) and Velcro cuff to provide tissue ingrowth (black arrow).

system, approximately 50% success at 30 days has been achieved in prospective randomized clinical trials compared with traditional pleurodesis methods.

This research was replicated with the Tenckhoff catheter, the pigtail catheter, and the Pleuracan device.⁴⁴⁻⁴⁶ Each of these devices controlled dyspnea in greater than 90% of the cases. Intermittent pleural drainage is an attractive option for patients in whom pleurodesis is less likely to occur because of the inability of the visceral pleura to touch the parietal pleura. As a consequence, this method is often used to complement sclerosis options at various centers.

Pleuroperitoneal Shunting. Another way to drain pleural fluid is to pump it into the peritoneal cavity using a device similar to that crafted to drain ascites into the venous system. This generally requires the patient to pump the shunt chamber (Fig. 30-8) at least 20 times four

times a day and perhaps more because of the need to overcome the negative intrapleural pressure.⁴⁷

More than 80% of patients reported excellent results with this method, and it obviated the need for an appliance to traverse the skin. Unfortunately, with this technology, at least 10% to 20% of the patients will occlude their shunt, possibly requiring revision; furthermore, determination of shunt obstruction may be difficult.⁴⁸ Otherwise, this shunt appears to have survival rates similar to those of talc pleurodesis. Also, there is generally no evidence of peritoneal deposits resulting from this pleuroperitoneal shunting technology. The decision to use the shunt can be made during thoracoscopy when pleural coaptation seems unlikely and placement of the shunt is relatively easy because the patient is under general anesthesia.

Sclerosis-Based Pleural Effusion Management

Generally, accelerating the process of pleurodesis (which might not occur by prolonged drainage alone) is done by accessing the pleural space, draining most of the fluid, and then inserting a substance that increases the inflammatory response and thus causes intense adhesions within the pleural envelope. There is controversy regarding how pleural fluid characteristics affect the success of pleurodesis or the prognosis of the patient. For instance, investigators have shown that a low pleural fluid glucose (<60 mg), low pH (<7.2), low performance status (Karnofsky score < 70), massive effusion, and high pleural LDH levels (>600 U/liter) are associated with a higher rate of failure with pleurodesis efforts. These values also predict positive pleural fluid cytology and a poor overall prognosis.⁴⁹ However, other investigators have contradicted this finding particularly with respect to pleural effusion pH.⁵⁰ Experimental evidence supports the concept that the inflammatory effect needed by some sclerosant agents is inhibited by steroid use, thereby decreasing the effectiveness of the pleurodesis.⁵¹

Rolling the patient into different positions after instilling the desired sclerosant is another common practice. This is unnecessary in patients with normal pleural spaces in whom aqueous sclerosing agents were used. Rapid intrapleural dispersion occurs in just one position as demonstrated by radiopharmaceutical labeling and nuclear medicine imaging.⁵² However, when the pleural space is loculated or there is lack of full lung expansion, rolling may be useful. Sclerosing agents that are particulate, like talc slurry, might have more uniform distribution by rolling, but this has been disproved in one small prospective trial.⁵³ There also appears to be variations in the practice of pleurodesis with surgeons more likely to use an agent such as talc and other physicians using bleomycin or cycline-based drugs.

Another practice that is controversial is the need for the pleural effusion drainage rate to taper off before instilling a sclerosing agent. This may be unnecessary. Investigators have shown that the daily amount of pleural fluid drainage is much less useful than having full pleural fluid evacuation and lung reexpansion on chest roentgenogram.⁵⁴ Pleurodesis appears to have only a minor

FIGURE 30-8 ■ Pleuroperitoneal shunt. **A**, Diagram of shunt position and demonstration of proximal and distal obstruction. **B**, Roentgenogram of lower chest and upper abdomen, showing left pleuroperitoneal shunt (*arrows*) with chamber placed at costal margin for patient self-pumping. **C**, CT image showing the catheter (*arrows*) in the left lower pleural space. This image was obtained 3 months after shunt placement in the patient whose left lower lung loculated pleural breast carcinoma effusion as depicted in [Figure 30-2B](#). (**A**, Reprinted with permission from Ponn RB, Blancaflor J, D'Agostino RS, et al: Pleuroperitoneal shunting for intractable pleural effusions. *Ann Thorac Surg* 51:605–609, 1991.)

adverse effect on respiratory function, although the studies on this are limited.⁵⁵ Finally, whereas sclerosis of the pleural cavity is generally practiced on inpatients, there have been successful outpatient pleurodesis programs.

When pleurodesis is performed as an inpatient procedure, a chest tube is generally inserted. Chest tube size can vary significantly, ranging from 20 to 36 Fr

depending on local institution or operator preference. Also, there appears to be considerable variation in sedation practices with occasional episodes of high discomfort and anxiety during the insertion of chest tubes. Generally, patients with dyspnea from malignant effusions are not decompensated enough to require emergent placement without analgesic preparation. It is appropriate to establish a protocol to standardize intravenous sedative

and analgesic use to supplement the generous use of local anesthetics during placement of a chest catheter.

The trend has been toward the use of smaller catheters, both for drainage and for the pleurodesis of malignant pleural effusions. In a prospective randomized study, a 12-Fr catheter was comparable to a standard large-bore tube.⁵⁶ This result has been reproduced in other studies using both inpatient and outpatient pleurodeses with the pigtail, Cystofix, Elecath, and PleurX catheters and talc, doxycycline, or similar traditional sclerosing agents.

Chemical Sclerosis—Talc. Talc was first used to create pleural adhesions in 1935 for tuberculosis management, and approximately 25 years later, it started to become popular for controlling malignant effusions. Generally, there are two ways to administer talc into the pleural space. One is in an insufflated powder (talc poudrage) and the other is instillation of particulate slurry with talc in a liquid vehicle. The dose of talc needed depends somewhat on the route of delivery and its preparation method. A fine powder from an aerosol gives a broader distribution with less mass (Fig. 30-9). Nevertheless, reported successful talc pleurodeses generally used between 2 and 8 g with a dose of 5 g being the most common used in multicenter trials.

Talc is often prepared preferentially in the hospital pharmacy rather than purchased from expensive vendors.

In fact, the cost compares favorably with that of most other agents. The use of purified but not sterilized talc may be acceptable because a tremendous inflammatory response kills contaminating bacteria. Nevertheless, the standard, preferred practice is to use talc sterilized by prolonged baking at 132° C, ethylene oxide sterilization (talc in cellophane pouches), or gamma radiation.

Although the use of talc for malignant pleural effusions has become widespread and is considered a safe clinical practice, some patients sustain an inflammatory response severe enough to cause respiratory insufficiency. Such responses have prompted experts to question its use. Clinical outcomes and laboratory testing show that talc administered intrapleurally is distributed systemically. The extent to which this might adversely affect somewhat frail patients who receive it is unclear. Some investigators have suggested that the patient should be observed as an inpatient for up to 72 hours after its use. Talc causes mesothelial denuding and an exudative neutrophilic pleural effusion similar to what occurs with the tetracycline class of sclerosis agents. For some tumors, such as mesothelioma, talc may also induce apoptosis. On the other hand, if there is evidence of increased fibrinolytic activity, then talc sclerosis may be less effective.

Table 30-3 lists good to excellent results of talc and other sclerosant agents in noncomparative studies. Hospital stays ranged from 3.3 to 4.4 days.^{57,58} Associated

FIGURE 30-9 ■ **A**, Thoracoscopic image of left chest before insufflation of talc. mortality ranges from 0% to 16% and morbidity ranges between 4% and 14% with respiratory complications being most frequent.

When talc is tested in comparison trials (Table 30-4), the results are not as favorable but still are equal or

superior to other common pleurodesis methods. Most of these investigations had good risk profiles with complication rates less than 20% and mortality attributed to the talc less than 5%. Are the differences in results dependent on the patient population or, perhaps, the method or composition of the talcum powder used? Particle size might affect dissemination. At least 20% of the patients who receive talc pleurodesis will have a transient interstitial haziness occur on the chest roentgenogram, possibly from endothelial damage and capillary leak syndrome. Talc slurry was thought to be a riskier delivery route because there seemed to be more anecdotal reports of respiratory distress associated with this method. Some investigators believe that intraoperative talc leads to shorter hospital stays. Another development is the use of awake anesthesia with a thoracic epidural, purported to decrease hospital length of stay and hasten recovery.⁵⁹ A prospective study has not shown a significant difference between talc poudrage administered in the operating room compared with bedside talc slurry based on 30-day prevention of an effusion.⁶⁰

Chemical Sclerosis—Cycline Drugs and Bleomycin. Multiple doses of chemical sclerosants have been studied, but a single dose is probably sufficient. A dose of tetracycline at 20 mg/kg was found to be effective as a single-dose regimen.⁶¹ Now doxycycline is available for clinical use instead of tetracycline. A dose of doxycycline is typically 500 mg in 100 to 200 mL of 0.9% saline. Although there has been interest in using cycline-based drugs intraoperatively, there is no advantage to this over bedside use. Results of noncomparison studies with tetracycline and bleomycin are presented in Table 30-3.

Bleomycin, in general, shows success rates that are equivalent or just less than those of talc pleurodesis. Pleural effusions from breast tumors may respond better than those of other tumors to this drug. Many times these drugs may work better in the pleural cavity than in other spaces such as the peritoneal cavity.

*Most investigators defined 100% success as complete or near complete control of pleural effusion at 30 days after pleurodesis based on both symptom control and repeat chest imaging. Although 1 month was a uniform interval for assessing this endpoint, some investigators used longer follow-up. Studies also differed on whether early deaths were considered failures.

TABLE 30-4 Randomized Trials of Common Sclerosant Agents and Percent Success*

*Most investigators defined 100% success as complete or near complete control of pleural effusion at 30 days after pleurodesis based on symptom control and repeat chest imaging.

[†]Multicenter trial.

Pain and transient fever occurred in 5% of patients after intrapleural instillation in one multicenter trial.⁶² In other studies, the fever occurred in as high as 60% of patients. It is unclear why there is so much variation in the reporting of these side effects.

Reports of pleural sclerosis need to be compared based on how long the treatment effects are followed. One investigation found 70% long-term success with combined bleomycin and tetracycline. Although a favorable early result was found with either agent, after 4 months the single-sclerosant success rate fell to 25% to 35%.⁶³

Other Sclerosing Compounds. Other compounds have been used, including three doses of *Corynebacterium parvum* (7 mg in 20 mL saline). Good results (76% to 100% success) were obtained, but this drug is no longer available. Intrapleural interferon- β (5 to 20 million units, maximum of three administrations) can be used alone, but there is only a 30% remission rate. Yet, when interferon- β is cycled with immunotherapy such as interleukin-2 and interferon- α , a 56% to 70% response rate occurs.⁶⁴ Tumor necrosis factor therapy yielded an 87% recurrence-free rate at 4 weeks with a dose of 0.15 to 1.01 mg/patient. These patients have flu-like symptoms, including fevers, chills, and fatigue.⁶⁵

Radiopharmaceutical Interventions

Radioactive compounds were used in the 1960s to control malignant pleural effusions, and they have gained renewed interest. The most commonly used is an intracavitary colloidal suspension of chromic phosphate (^{32}P) because of its safer emission and faster decay compared with elements such as gold. Results of these therapies in uncontrolled trials have 75% success rates.⁶⁶ Generally, a dose of 6 to 12 mCi of ^{32}P is used, which has a half-life of 14 days. A therapeutic thoracentesis (maximal drainage) is performed with a temporary thoracentesis catheter. The catheter remains in place until the ^{32}P is instilled. It is then flushed and withdrawn. The patient may then be discharged if there are no complications.

Mechanical Abrasion or Laser

Limited data exist regarding the use of mechanical pleural abrasion that is effective for other types of pleural disease such as pneumothorax. Experimental data suggest that the mechanical abrasions are no better than the addition of sclerosing agents such as talc. Similarly, laser treatments that cause superficial pleural destruction are probably not as effective in controlling effusions. Both are inhibited by their erratic effects in poorly healing neoplastic tissue.

Pleurectomy

The poor prognoses of patients with malignant pleural effusions limit enthusiasm for aggressive surgical options given the anticipated recovery times for such operations. However, the less invasive therapies noted earlier are used when thoracoscopy is needed to achieve a directed diagnosis of the pleural pathology. The use of

FIGURE 30-10 ■ Video-assisted thoracic surgery (VATS) image of parietal pleurectomy. L, Lung; P, parietal pleural peel.

thoracotomy and pleurectomy is accepted more for patients with malignant mesothelioma in whom early mortality from distant metastases is less certain. The mortality rate for pleurectomy of malignant effusions is at least 12%. Patients were considered for pleurectomy if they failed traditional drainage and sclerosing agents, had trapped lung, or were diagnosed as having malignant pleural effusion or pleural carcinomatosis at the time of thoracotomy. Nevertheless, these indications are now unusual outside a clinical trial. To reduce the concern regarding thoracotomy morbidity, there is interest in VATS pleurectomy (Fig. 30-10), which results in a shorter hospital stay and good effusion control. In a series of patients who underwent VATS pleurectomy,⁶⁷ there was 0% mortality with a mean hospital stay of 5 days. Six of 19 patients died within 12 months, and of the remaining 13 patients, 2 developed recurrent effusions.

Prognosis and Future Trends

The prognoses of patients with malignant effusions vary among clinical settings because of population variations in primary cell types and regional preferences in therapies used to control effusions. A survival rate of less than 50% at 6 months and 6% at 2 years after malignant pleural effusion diagnosis is typical. Also in these series, patients treated only by serial thoracenteses rather than more aggressive therapies had a particularly short survival (13.9 weeks). Alternatively, a longer interval between the initial diagnosis of cancer and the malignant effusion favors survival.

Breast cancer effusions are associated with a more favorable survival rate, particularly when they are estrogen receptor positive and the cells show a morula clustering pattern on cytology. The presence of large clusters of malignant cells on smears also has a favorable prognosis in other cancers. Unfavorable tumor surface receptors adversely affect prognosis (see “[Immunocytochemistry and Special Chemistry](#)”).

As with other treatment modalities, patient performance status is an important factor in determining optimal therapy. A Karnovsky score of 70 or higher is preferred before more aggressive surgical approaches (e.g., thoracoscopy) that require general anesthesia are taken. This yields a survival rate that makes the morbidity risk tenable.

Occasionally, trivial malignant effusions are discovered with minimal nearby carcinomatous pleuritis at the time of thoracotomy. If there is only a small primary tumor with little other regional disease, it may be reasonable to perform a formal resection if the patient has good pulmonary function. Although this approach is controversial, the logic for taking this approach follows from the finding that patients who have occult pleural metastases treated by pleural washings may have prolonged survival times or even cure. Accordingly, for patients with minimal pleural carcinomatosis and N0 tumors, there is interest in performing ablative therapy of the pleura to improve cancer control and possibly effect a cure. One of these treatments has been pleurectomy and intracavitary photodynamic therapy, which has been used to treat mesothelioma and may also be useful for treating primary lung cancer. A phase II trial on carefully selected patients demonstrated a 6-month local control rate of 73% and a median survival of 21.7 months.⁶⁸

Hyperthermic chemotherapy and hypotonic chemotherapy are other investigational methods of effusion control. Experience in mesothelioma work has led to use of hyperthermic pleural chemoperfusion in isolated metastatic pleural disease with favorable results in small series.⁶⁹ Thrombolytic agents may disrupt loculations for more effective pleurodesis or pleural ablation therapy. Transfer of lymphokine-activated killer cells improved tumor lysis in the pleural space, and intrapleural interleukin-2 induced a 37% complete response in a multi-institutional study, possibly by restoring the immunocompetence of effusion-associated lymphocytes.⁷⁰ Cytokine therapy, particularly the use of VEGF receptor blocker, can control some pleural effusions. In related research, indomethacin was shown to block prostanoïd-related endothelial cell permeability associated with adenocarcinomas. Intrapleural steroids, however, do not slow effusion reaccumulation. Gene therapy approaches, such as suicide gene therapy, continue to show steady progress but should still be considered investigational.⁷¹

Finally, intrapleural chemotherapy can control effusions without pleurodesis, per se. Mixed results have occurred with agents such as cisplatin and cytarabine, and doxorubicin. One of the trials by the Lung Cancer Study Group showed a combined complete and partial response at 3 weeks of 49%.⁷² More commonly, systemic chemotherapy is administered; recent drugs used for this include gemcitabine and vinorelbine or combinations with cisplatin, ifosfamide, and irinotecan. Zoledronic acid and hypotonic cisplatin therapy have also been proposed.^{73,74} Gene therapy is yet another strategy being explored.⁷⁵

Fusing of a sclerosing agent with a chemotherapy agent is another novel approach. A bioadhesion compound linked to Adriamycin achieved a 100% response rate in 14 patients in a preliminary report.⁷⁶ Similarly, microspheres can deliver chemotherapy intrapleurally at high local concentrations with low systemic exposures.

Diverse managements are offered for patients with malignant pleural effusions. Optimally, the treatment conforms to the patient's anticipated survival based on histologic diagnosis, molecular markers, extent of metastatic disease, and other comorbidities. Despite some promising research, the overall prognoses of these patients are limited and therapy should focus on improving quality of life. Accordingly, less invasive outpatient small catheter-based methods are replacing inpatient therapies such as the traditional chest tube with talc slurry. A randomized controlled trial (CALGB 30102) was designed to compare chest tube talc slurry (inpatient) with intermittent small catheter drainage (outpatient). However, this study closed early because of poor accrual; nevertheless, data analysis demonstrated better palliation by catheter-based drainage.⁷⁷ A cost-effectiveness analysis performed by Puri and colleagues suggests that tunneled catheters are the most cost effective in patients with limited prognosis and bedside pleurodesis is most cost effective in patients with better prognosis.⁷⁸

MALIGNANT PERICARDIAL EFFUSIONS

Pericardial effusion is the most common cardiac problem in patients with malignant disease and is reported in 1.5% to 21% of patients with cancer.⁷⁹ Nonmalignant conditions also cause pericardial effusions in patients with cancer. Examples of these conditions are infection, uremia, congestive heart failure, hypothyroidism, and autoimmune disorders. Radiation, drug-induced pericarditis, and idiopathic pericarditis are also known causes of pericardial effusions.

The most common malignancies to involve the pericardium are metastatic lung cancer, breast cancer, leukemia, lymphoma, and melanoma. Less commonly, secondary involvement by esophageal, gastric, colonic, oral, nasopharyngeal, prostate, and ovarian carcinoma may be seen. Primary tumors of the pericardium are rare and include mesothelioma, fibrosarcoma, angiosarcoma, and malignant teratoma.

Mechanism

Tumors spread to the pericardium by direct extension or by hematogenous or lymphatic spread. Mediastinal lymph node metastases subsequently spread to the pericardium by retrograde movement through lymphatic vessels draining that space. Increased visceral pericardial fluid production may result from direct involvement of the serosal surface by tumor. Flow obstruction by tumor increases lymphatic and venous hydrostatic pressure, which also drives pericardial fluid accumulation. The hemodynamic consequences of a pericardial effusion depend on its rate of accumulation and the pericardial compliance. Thus, large effusions may cause no symptoms if they accumulate slowly within compliant pericardia.

Evaluation

Frequent pericardial effusion symptoms are dyspnea, cough, and chest pain. Physical examination findings are

tachycardia, pulsus paradoxus, diminished heart sounds, elevated jugular venous pressure, hypotension, and pulsus alternans. Pericardial tamponade is more likely after rapid accumulations of fluid and may be the initial clinical presentation of malignant pericardial disease.

The chest radiograph often shows an enlarged cardiac silhouette, mediastinal widening, or hilar densities. Alternatively, a normal plain radiograph does not exclude pericardial effusion. Electrocardiographic effusion criteria are sinus tachycardia, nonspecific ST segment or T wave changes, low-voltage tracings, and electrical alternans.

Echocardiography is very sensitive in detecting the presence of fluid and has become the most useful tool for diagnosing pericardial effusions (Fig. 30-11). Right atrial or right ventricular compression with decreased left ventricular dimension and failure of the inferior vena cava to collapse on deep inspiration suggests hemodynamic compromise. The echocardiogram also guides pericardiocentesis, drainage catheter placement, or both, safely. Cytologic examination of the pericardial fluid may then be performed. The rate of positive cytologic results reported in published series ranges from 57% to 100% among patients with malignancy.⁸⁰ Both CT and MRI provide excellent anatomic detail of the pericardial space but do not yield physiologic or functional information (Fig. 30-12).

Treatment

Various therapeutic interventions are used alone or in combination to treat patients with malignant pericardial effusions. One of the main objectives is obliteration of any potential pericardial space by fusion of the epicardium and pericardium. Patient performance status, medical comorbidities, malignant disease stage, prognosis, and response to other cancer treatments influence selections of these options.

Pericardiocentesis provides immediate decompression of the pericardial space and is usually performed with echocardiographic guidance. Hemodynamic impairment is thereby relieved but can recur quickly. Recurrence

rates as high as 25% have been reported.⁸¹ Thus, this procedure is seldom durable enough except for terminal patients with brief anticipated survival.

A pericardial catheter left in place at the time of pericardiocentesis allows drainage of additional fluid with or without administration of a sclerosing agent. Numerous investigators have induced pericardial sclerosis to prevent pericardial effusion recurrences. Some of the agents administered were thiopeta, tetracyclines, OK-432 (an immunomodulator), bleomycin, aclarubicin, mitomycin C, 5-fluorouracil, and radiocolloids such as ³²P and ¹⁵⁴Au. Doxycycline may produce intense pain and, as with bleomycin, may produce a febrile response in a significant number of patients. Thiopeta does not cause pain and rarely evokes a fever. It is inexpensive and is the sclerosant of choice at some centers because of these advantages. Intrapericardial sclerosis has an overall success rate over 80%.⁸¹ A few centers have used intrapericardial radiocolloids, but their popularity is limited in part because of logistic problems related to their administration. Intrapericardial interferon has also been used.⁸² It reportedly enhances cell-mediated cytotoxicity and has an antiproliferative effect. Colchicine has also been described to have an inhibitory effect on leukocyte chemotaxis and decreases the production of interleukin-1 by monocytes.⁸³ These effects have been exploited in the use of colchicine in the treatment of refractory malignant pericardial effusion. The minimally invasive nature of these catheter-based interventions is attractive and reduces the recurrence rate after simple pericardiocentesis to an acceptable level. When less invasive options fail, surgical treatment can be offered to appropriate candidates.

Of the surgical options, subxiphoid pericardial “window” creation has been used most extensively (Fig. 30-13). It can be performed using local or general anesthesia, it has low complication rates, and it does not require single-lung ventilation like some thoracoscopic methods.

Success rates over 90% have been reported.⁸¹ Much of the pericardial fluid drainage occurs in the space posterior to the ascending aorta through abundant

FIGURE 30-11 ■ Echocardiogram shows a large pericardial effusion (arrows). D, Diaphragmatic pericardium; V, ventricle.

FIGURE 30-12 ■ CT scan shows moderately large pericardial effusion (arrows). Ao, Aortic root; L, liver dome; V, atrioventricular junction with adjacent pulmonary outflow tract.

FIGURE 30-13 ■ **A**, Relation of pericardial effusion to planned subxiphoid incision (arrow). **B**, Large pericardial window has been resected. Exposure can be facilitated by partial excision of the subxiphoid cartilage. Drainage may be facilitated by placement of a drainage tube, opening of the pleural spaces, or a preperitoneal space, depending on the surgeon's preference. **C**, Exposure can also be facilitated by a self-retaining retractor system that lifts the costal margin and sternum anteriorly to expose the superior pericardium. The model is positioned under partial ring of the Bookwalter retractor system with small blades that provide this traction. Black dashed line shows the costal margin and the white dashed line overlies the xiphoid process, denoting the planned incision. (**A** and **B**, Reprinted with permission from Ravitch M, Steichen F: *Atlas of general thoracic surgery*, Philadelphia, 1988, WB Saunders, p 175.)

carinal lymphatic systems. A relatively small tumor burden in that space (which is not visible to surgeons performing subxiphoid pericardial windows) may create an effusion. This accounts for some pericardial window specimens that do not show malignancy by pathologic review.

Thoracotomy may be used to either create a pleuro-pericardial window or perform pericardiectomy. The latter has been claimed to have the greatest durability of all the surgical procedures. However, it requires general anesthesia and optimal single-lung ventilation, and it has relatively high morbidity and mortality rates.

Thoracoscopic approaches aim to provide the same quality of pericardial drainage without the morbidity of a thoracotomy.⁸⁴ Thoracoscopic approaches have been well tolerated in very ill patients but still require single-lung ventilation and general anesthesia. When both pleural and pericardial effusions are present, a thoracoscopic approach should be favored (Fig. 30-14). This permits treatment of both spaces. Also, excellent

visualization of the thoracic cavity permits directed biopsies in undiagnosed cases.

Percutaneous balloon pericardial window creation has been reported.⁸⁵ Complications included pleural effusions requiring drainage, transient fever, and small pneumothoraces. This was performed with patients under local anesthesia and usually permitted prompt hospital discharge.

The Denver pleuroperitoneal shunt has also been used to drain pericardial effusions into the peritoneal space.⁸⁶ This requires only local anesthesia and a short hospital stay. The patients need to compress the pumping chamber of the device several times daily. Possible shortcomings of this drainage method include lack of patient cooperation and shunt thrombosis.

Passive pericardioperitoneal shunting can be accomplished using a video-assisted technique.⁸⁷ This technique essentially involves a laparoscopic approach to creating a generous transdiaphragmatic pericardial window without an external drain.

FIGURE 30-14 ■ **A**, Trocar positions in preparation for creation of a thoracoscopic pericardial window. The patient is in the decubitus position. The camera trocar site lies most posteriorly, and the remaining two sites are used for manipulating instruments. **B**, Thoracoscopic image of left thoracoscopic pericardial window (left chest). *H*, Heart; *P*, pericardium. (**A**, From Inderbitzi R, Furrer M, Leupi F: Pericardial biopsy and fenestration. *Eur Heart J* 14:135–137, 1993.)

Chemotherapy and radiation therapy can be quite effective in patients with neoplasms that are sensitive to these modalities. These therapies can be used in conjunction with direct pericardial interventions.

The choice of procedure is patient dependent and must be individualized. No modality is clearly superior to others, but the degree of invasiveness, morbidity, and cost vary widely. The clinical focus should be placed on providing rapid and durable relief from the effusion with the least possible morbidity.

PLEURAL EMBRYOLOGY AND ANATOMY

The pleura is a thin continuous membrane that separates during embryologic development into two layers as the developing lung buds encroach on the pleural cavity. The component of the pleural membrane that envelopes the lung is called the visceral pleura, which then continues as a contiguous serosal layer, called the parietal pleura, to cover the chest wall, the mediastinum, and the diaphragm. These layers fuse at the hilum, creating the pleural space. The pleural space contains a small quantity of glycoprotein-rich fluid that allows the opposing pleural surfaces to glide over each other during respiration. These pleural membranes are derived from the mesoderm during embryogenesis; the separation by the ingrowth of the lung bud permits the parietal pleura to fuse with the ectoderm to form the somatopleure and the visceral pleura to fuse with the endoderm to form the splanchnopleure. Thus, all three germ layers are represented in the histogenesis of the pleurae, which explains

the later de-differentiation of pleural tumors into both epithelial and mesenchymal elements.

The blood supply of the parietal pleura emanates from systemic sources: intercostal arteries, subclavian artery, internal thoracic artery, and phrenic arteries. The visceral pleura derives its arterial blood supply from the bronchial arterial circulation and from the lung parenchyma. The lymphatic drainage for the parietal pleura follows the arterial blood supply and drains to systemic sources. The visceral pleura drains into the pulmonary parenchyma. Naturally occurring pores or stomata in the caudal aspect of the parietal and mediastinal pleurae transfer particulate matter into lymphatic channels for drainage. Most of the fluid that accumulates in the pleural space is derived from the lung and is absorbed by the parietal pleura. The visceral pleura is devoid of somatic innervation, whereas the parietal pleura has a rich network of somatic, sympathetic, and parasympathetic neural innervation.

The pleural membrane is thin and translucent. It is composed of five separate layers: (1) the mesothelial layer (flattened mesothelial cells joined by tight junctions),

(2) a thin submesothelial connective tissue layer, (3) a superficial elastic tissue layer, (4) a loose subpleural connective tissue layer in which run lymphatics, nerves, arteries, and veins, and (5) a fibroelastic layer that is adherent to the underlying structures (lung, mediastinum, diaphragm, and chest wall). The mesothelial cell features long slender microvilli that extend into the pleural space and are believed to release hyaluronic acid into the pleural fluid.¹

The pleural response to injury is characterized by edema and exudation of protein and neutrophils. This response is known as an exudative pleural reaction. It is orchestrated by the release of inflammatory mediators (cytokines, chemokines, oxidants, and proteases) from mesothelial cells, which also have phagocytic capabilities. Lesser inflammatory conditions can be resolved by the absorption of inflammatory products by mesothelial cells aided by the lymphatic evacuation of fluid and particles. Severe or persistent damage encourages a submesothelial fibroblastic response and the formation of dense adhesions.

The pleural reaction can occur in response to an infectious or a noninfectious injury, usually acquired through the respiratory system. Infectious organisms are associated with empyema. However, the visceral pleura responds to autoimmune diseases, drug reactions, radiation, or pneumoconiosis by creating cytokines (transforming growth factor- β [TGF- β] and tumor necrosis factor- α [TNF- α]), which in turn lead to the formation of a fibrin matrix. Asbestos, silica, and coal dust are associated with the development of circumferential plaques of dense hyaline fibrosis on the parietal pleural surface that typically involve the diaphragm and chest wall.

ASBESTOS-ASSOCIATED PLEURAL PATHOLOGY

Biologic Capabilities of Asbestos Fibers

Asbestos is divided into two main types based on fiber length and other physical properties that may account for its biopersistence in humans. The fibers of the first type are short and serpentine. Chrysotile (or white asbestos) is the predominant member. The second type, known as amphibole asbestos, has long, thin, straight fibers. It has several subtypes, including crocidolite, actinolite, tremolite, anthophyllite, and amosite.² Approximately 95% of the asbestos currently used worldwide is chrysotile. The remaining 5% is amosite and crocidolite, although these groups of fibers are commonly mixed together.³

Two conflicting theories have been advanced to explain the oncogenic potential of asbestos fibers based on their physical properties of dimension, shape, and length. The amphibole hypothesis proposes that amphibole fibers owe their durability and their biopersistence in the lung to their long length. Proponents of this hypothesis believe that the short serpentine chrysotile fibers are broken down and cleared too quickly to provoke cancer.⁴ The Stanton theory postulates that amphibole asbestos is carcinogenic because the long fibers are able to penetrate deeper into the pleura, where they come in contact with

and incite mesothelial cell proliferation.⁵ Whatever the cause, it appears that chrysotile fibers are cleared from the body by macrophages much more quickly than are amphibole fibers, which can remain in the lung for many years after exposure, accounting for their high degree of biopersistence.

There is evidence that the biopersistence of asbestos fibers is associated with malignancy in animals^{6,7} and in humans.⁸ Although consensus has not been reached on the precise carcinogenic potential of the different fiber types, or the level or length of exposure needed for the malignant transformation to mesothelioma, an expert panel (level 4 evidence) published an opinion on this matter in 2003. The consensus decision of this panel suggests that the longer, biopersistent fibers associated with amphibole asbestos (particularly, crocidolite) have greater carcinogenic potential than the short fibers of the serpentine asbestos.⁹

Epidemiology of Mesothelioma

The causal association between asbestos exposure and the later development of pleural tumors is strong. However, the lack of a clinically recognizable, premalignant, non-invasive form of malignant mesothelioma, coupled with the difficulty of obtaining invasive biopsy material, has hampered the identification of the agent or agents responsible for initiating or promoting the development of pleural tumors *in vivo*. Thus, much of the current knowledge is empirically derived from three sources: epidemiologic data, *in vitro* investigation of asbestos and mesothelial cell lines, and retrograde assumptions made from mesothelioma chromosome studies.

Malignant mesothelioma was first identified as a discrete diagnosis in 1870.¹⁰ The name was coined in the 1930s.¹¹ Suspicion of an association between asbestos exposure and mesothelioma development was initially documented in the medical literature between 1920 and 1950.¹²⁻¹⁴ Despite the numerous case reports, it was not until 1960 that Wagner and colleagues reported a series of cases that demonstrated a strong association between mesothelioma and occupational exposure to asbestos in asbestos miners in South Africa.¹⁰ A clear link between asbestos exposure and pleural tumor development was documented in the United States by Selikoff and colleagues in the 1960s and 1970s.^{15,16} Further evidence of this association followed, with multiple case-control series from 1965 to 1975. These reports were summarized in an epidemiologic review of mesothelioma by Britton.¹⁷ In this review, the most notable risk of mesothelioma was associated with occupational exposure to asbestos, primarily in shipyards where crocidolite asbestos was used in naval insulation materials. Other defined exposure groups with varied relative risks of mesothelioma development included workers who installed insulation and workers in the asbestos product manufacturing industry or in heating and construction industries.¹⁷ After Wagner's publication, further worldwide case series comparing amphibole and chrysotile fiber exposures from 1980 to 1999 confirmed the association of asbestos exposure (particularly amphibole fibers) and mesothelioma. Even chrysotile miners were identified to be at high risk

for mesothelioma, although contamination of the chrysotile asbestos by amphibole fibers (particularly tremolite) as the true cause of disease in these miners has been questioned.^{17,18}

Based on the suspicion of an association between asbestos and cancer development, industrial regulations emerged. As early as 1932, the United Kingdom issued the first anti-asbestos regulation, titled "Asbestos Industry Regulation 1931." Crocidolite asbestos was not banned in the United Kingdom, however, until 1970. By 1980, most western European countries had followed suit. The U.S. Environmental Protection Agency listed asbestos as a hazardous air pollutant in 1971. By 1972, exposure limits for asbestos had been published, and by 1979 asbestos use was curtailed. Asbestos control or regulation in many other world regions has yet to be achieved.

The latency period (20 to 50 years) between exposure to asbestos and mesothelioma development is substantial.¹⁹ Although the epidemiologic data linking asbestos exposure to mesothelioma are clear, the lifetime risk of mesothelioma development in workers exposed to asbestos ranges from 4.5% to 10.0%.²⁰⁻²³ Thus, the lack of a strong, direct, quantifiable association between asbestos exposure and pleural tumor development impedes the prediction of individual disease development, and future predictions are relevant only in broad demographic terms.

Western populations were exposed to asbestos as an environmental hazard when it was used in an uncontrolled fashion in the shipbuilding and construction industries between 1940 and 1970. Despite worldwide attention by environmental regulatory bodies, the latency of the disease suggests that the peak incidence of the disease in Europe, North America, and Australia may be in the next 10 to 15 years.^{24,25} Prediction risks for mesothelioma development suggest that the disease will continue to increase in Europe, to peak in 2020, and thereafter to rapidly decline, because the workforce exposure should affect only the population born before 1950 (assuming the commencement of work at age 20, when asbestos regulations were initiated).^{17,24} The prediction for a mesothelioma peak in the United States is 2004; Australia, 2015; and Japan, 2025. However, these assumptions do not include many unanticipated factors such as the attack on the World Trade Center in 2001, where an estimated 10 million New Yorkers were exposed to asbestos dust.^{26,27}

Population Exposure

Individuals with asbestos disease can be divided into four groups based on the degree of exposure to asbestos: direct occupational exposure, secondary occupational exposure, passive occupational exposure, and nonoccupational exposure.

The first group comprises individuals with direct exposure either through work or by direct inadvertent exposure to asbestos fibers. An example of this exposure group is the miners of asbestos in Wittenoom, Australia. These miners were exposed at work, but because asbestos was used in lieu of grass to cover the schoolyards and playgrounds, their children also received direct exposure.²⁵

The secondary exposure group represents persons whose exposure could be termed as *occasional*, such as plumbers, carpenters, navy personnel, and installers of asbestos as insulation.

The third group represents those who are passively exposed through other family members who work directly with asbestos and carry the fibers home on their clothing. This group includes persons in close contact with the first two groups (e.g., wives of asbestos workers).²⁸

A small number of individuals have mesothelioma but no history of occupational exposure to asbestos. Some may have contacted asbestos fibers in their natural habitat,²⁹ or they may have a genetic predisposition.^{30,31} It has been postulated that simian virus 40 (SV40) plays a synergistic role with asbestos in the development of mesothelioma, either as a clastogenic transformer (an inducer of chromosomal damage) or as a cytologic protector, which permits chromosomally damaged cells to survive and propagate rather than die (apoptosis).^{32,33} SV40 was identified as a contaminant in polio vaccines from 1950 to 1963, and the extent of its role in mesothelioma development is still controversial and undetermined.

Finally, 2% to 5% of mesothelioma cases arise in a pediatric population, which suggests a genetic rather than an environmental cause of mesothelioma in these individuals.³⁴

Pathogenesis of Asbestos Fibers

Benign asbestos-related pleural disease is thought to manifest as either discrete parietal pleural plaques or diffuse disease involving visceral pleural hyperplasia and fibrosis.³⁵ The mechanism whereby asbestos fibers reach the parietal pleura to evoke pleural plaque formation is unknown. However, as described earlier, it is suspected that the inability of pulmonary macrophages to phagocytose these particles is a result of their length and that the fibers burrow through the lung and eventually come into contact with the mesothelial cells in the pleural membranes. Several theories have been proposed to explain how the fibers pass from the visceral to the parietal mesothelial cells. There are several putative causes. The fibers may protrude through the visceral pleura, abrading and irritating the parietal pleural surface. The fibers may migrate across the pleura from the visceral to the parietal surface, or they may disseminate via lymphatic drainage to the parietal mesothelial cells.^{27,35}

The effect of asbestos on mesothelial cells is complex, multifactorial, and difficult to explain. It has been shown, for example, that human mesothelial cells often die in vitro after contact with, or phagocytosis of, asbestos fibers.^{36,37} A possible explanation is that asbestos fibers may induce the proliferation of cellular cytokines that have cytoprotective effects and that allow asbestos-transformed mesothelial cells to survive and proliferate. TNF- α expression has been shown to increase after mesothelial cells and macrophages are exposed to asbestos, and this factor may enable the asbestos-damaged cells to survive.³⁸ Fiber persistence may lead to chronic inflammation with increased cycles of cell growth that might induce cellular mitotic changes. These changes may

gradually cause the mesothelial cells to acquire genetic and epigenetic changes that lead to neoplasia. Even without directly interfering with the DNA machinery of the cell, these fibers may secondarily select for cells with oncologic potential.

In addition to inducing cellular proliferation, asbestos fibers have other cytologic and clastogenic properties that could lead to neoplasia. Incorporation of asbestos fibers into the mesothelial cell, for example, produces oxygen free radicals,^{39,40} cytokines, chemokines, and growth factors such as epidermal growth factor (EGF) and TGF- α .⁴¹⁻⁴³ These elements can promote the proliferation of mesothelial cells, rendering them more susceptible to DNA and genetic damage.⁴⁴ Asbestos induces phosphorylation of mitogen-activated protein (MAP) kinases and of the extracellular signal-regulated kinases (ERKs) 1 and 2 with increased downstream expression of tumor proto-oncogenes.⁴³

Asbestos fibers also have clastogenic properties—that is, they may act directly on the chromosomes.⁴⁵ They may sever or disrupt the mitotic spindle of cells, causing chromosomal abnormalities such as aneuploidy to occur.⁴⁶ Finally, they may induce epigenetic tumor suppressor silencing via promoter DNA CpG methylation, which permits tumorigenic cells to enter the cell cycle instead of halting them at the G₁/S interphase of mitosis.⁴⁷

Mesothelial Cell Neoplastic Changes Attributed to Asbestos Exposure

Retrograde analysis of molecular biologic changes in the malignant mesothelial cell has revealed several different areas of molecular variance from normal mesothelial cellular mechanics. These variations are thought to lead to neoplasia.

Chromosomal Abnormalities in Mesothelioma. Karyotypic alterations result from somatic mutations; however, gene deletions, gene silencing, and RNA editing are also common chromosomal aberrations in malignant mesothelioma. DNA sequencing techniques and comparative genomic hybridization permit discrimination between clonal proliferations of tumor cells.^{48,49} These techniques may also help in the histologic identification and sorting of mesothelioma subtypes. They may aid by distinguishing mesothelioma from similar-appearing tumors such as adenocarcinoma.⁵⁰ Whole-transcriptome, deep sequencing of single mesothelioma tumors has revealed unique individual tumor profiles of chromosomal and mRNA expression.⁵¹

These chromosomal changes in malignant mesothelioma often are multiple, leading to clonal proliferations that show individual variation (losses are more common than gains).⁵⁰ In mesothelioma, a common deletion occurs at the 9p21 locus. This occurs at a frequency of 70% in mesothelioma cell lines and in up to 22% of primary tumor specimens.^{52,53} This locus encodes two inhibitors of the cyclin-dependent kinases (CDKs)—namely, p16^{INK4a} (CDKN2A) and p15^{INK4b} (CDKN2B), which prevent the phosphorylation of retinoblastoma (Rb) protein. The Rb protein modulates cell entrance into the S phase from G₁ of the cell cycle.

Phosphorylation of this protein, which is prevented by CDK inhibitors, allows uncontrolled cellular entry into S phase. The 9p21 gene also codes for p14^{ARF}, which acts as a regulator for an important tumor suppressor oncogene, p53. This gene encodes tumor protein p53, which responds to diverse cellular stresses such as hypoxia, DNA damage, and oncogene activation, to regulate target genes that induce cell cycle arrest, apoptosis, senescence, DNA repair, or changes in metabolism. P53 protein is expressed at a low level in normal cells and at a high level in various transformed cell lines, where it is believed to contribute to transformation and malignancy. P53 is a DNA-binding protein containing transcription activation, DNA-binding, and oligomerization domains. It is postulated to bind to a p53-binding site and activate expression of downstream genes that inhibit growth and invasion and thus function as a tumor suppressor by initiating the transcription of genes leading to downstream effects on cell cycle arrest in G₀ and apoptosis. A downstream target of p53 is p21, a multifunctional CDK inhibitor. Loss of p21 expression is associated with decreased patient survival.⁵⁴ Also, there is a frequent loss of chromosome 22 in malignant mesothelioma.⁵⁵ The tumor suppressor gene *NF2* is located on this chromosome.

Tumor Suppressor Genes in Mesothelioma

Tumor Suppressor Genes and CDK Inhibitor Loss. Ironically, malignant mesothelial cells lack mutation of the two most common genetic mutations found in most cancers—namely, tumor suppressor genes *p53* and *pRb*.⁵⁶ The tumor suppressor gene *p53* is important for cell cycle arrest because it prevents propagation of DNA-damaged cells or genetically unstable cells. It acts by stimulating the expression of p21, which, in turn, acts as a CDK inhibitor. In an equivalent manner, the retinoblastoma gene (*Rb*), as noted earlier, also halts chromosomal synthesis and therefore tumor proliferation.

However, the chromosomal aberrations of malignant mesothelioma cells ultimately adversely affect these two tumor suppressor genes by upstream regulation of their gene products. Mutational deletion of the 9p21 locus in mesothelioma cells affects p14^{ARF}, an upstream regulator of p53. Deletional interruptions of this gene inactivate TP53-MDM2, which is extremely important for intrinsic cellular control of chromosomally damaged cells. Inactivation of this pathway by decreasing p21 gene products allows CDK to phosphorylate Rb protein, which then allows damaged cells to enter the S phase of the cell cycle.⁵⁷ Viral transduction of p14^{ARF} into mesothelioma cells in culture leads to increased production of p53 and p21, resulting in an increase in dephosphorylated Rb and G₁ arrest and an inhibition of mesothelioma cell growth.⁵⁸

In an equivalent manner, the loss of p16^{INK4a} leads to loss of CDK 4 and 6, leading to phosphorylation of *Rb* gene by the lack of CDK inhibition.⁵⁷ Deletion of p16/CDKN2A has been reported in greater than 70% of mesothelioma cells.^{50,59} As seen with p53, mesothelioma cells transfected with adenovirus expressing p16^{INK4a} demonstrate decreased phosphorylation of Rb,⁶⁰ leading to cell cycle arrest, cell death, and tumor regression.

Merlin and RAS-ERK Pathway. Changes in chromosome 22 may lead to altered expression of *NF2*, or somatic mutational changes may lead to *NF2* alterations, which occur in approximately 50% of patients with mesothelioma.⁶¹ *NF2* encodes for a protein named merlin (alternatively called schwannomin). This protein is important in the connection between the plasma membrane and the cytoskeleton of the cell and may act as a tumor suppressor gene by inhibiting the RAS-ERK pathway and inducing cyclin D1 expression. Inhibition or abrogation of *NF2* function and its downstream product merlin may lead to a lack of contact-dependent growth arrest,⁶²⁻⁶⁴ leading to tumor proliferation at the expense of neighboring normal cells.

Oncogene Activation in Mesothelioma. The transcription factors AP-1 and β -catenin are often upregulated in malignant mesothelioma; AP-1 is upregulated by Fra-1 which is a member of the Fos family of transcription factors. Fra-1 expression is increased in malignant mesothelioma cells, in response to asbestos or EGF, and reduced with inhibitors of ERK. Mesothelioma cells transfected with either an ERK inhibitor or a dominant negative Fra-1 reverse their transformed phenotype.⁶⁵

The transcription factor β -catenin is controlled by Wnt signaling, so that the presence of Wnt inhibits phosphorylation of adenomatous polyposis coli (APC) and axin, allowing persistence of β -catenin. Increased presence of β -catenin leads to nuclear binding of T cell factor/lymphoid-enhancer factor (Tcf/Lef) proteins with downstream activation of transcription factors. Mesothelioma cells have been shown to have altered APC expression,⁶⁶ and they may express upstream negative inhibitors of the Wnt pathway (Wnt inhibitory factor [WIF-1] and secreted frizzled-related protein [sFRP]).^{67,68} Extracellular signaling, through the overexpression of membrane disheveled proteins with downstream activation of β -catenin, may play an important role in malignant mesothelioma.⁵⁷

Epigenetic Maneuvers. Promoter methylation has been shown to be effective in inactivating WIF-1 and sFRP.^{69,70} Hypermethylation of DNA is a common epigenetic method of inhibition of tumor suppressor gene function.^{71,72} In the context of asbestos exposure, however, there may be a dose-dependent increased induction of methylation as a result of asbestos fibers.⁴⁷ The precise mechanism for hypermethylation of this phenotypically important pathway is still not established. It may also be directly attributable to the clastogenic properties of asbestos fibers, or alternatively to repeated inflammatory insults of asbestos-generating reactive oxygen species, which may lead to increased mitotic stimulation and promoter methylation. Acquired generations of accrued genetic and epigenetic chromosomal changes leading to malignancy may thus be induced.⁴⁷

Growth Factors in Mesothelioma. Platelet-derived growth factor (PDGF) chains A and B increase in response to asbestos exposure; they have been implicated in the development and progression of malignant mesothelioma.^{50,73} Asbestos also induces autophosphorylation of EGF receptor (EGFR). This may result in the activation

of the MAP kinase cascade and ERK1 and ERK2 kinases, leading to expression of proto-oncogenes that encode members of the fos-jun and activator protein 1 families.⁴³ Hepatocyte growth factor (HGF) can promote cell growth and migration mediated via downstream AKT and ERK pathways by binding to its receptor c-Met. Circulating levels of this growth factor are elevated in patients with mesothelioma, so inhibition of HGF receptor c-Met may be a therapeutic option.⁷⁴ EGFR (member of the ErbB family of tyrosine kinase receptors) is overexpressed in malignant mesothelioma in association with angiogenesis and proliferation.⁷⁵ Multiple ligands can bind to and activate this receptor, leading to intracellular tyrosine kinase autophosphorylation and signaling pathways of cell proliferation, differentiation, and immortality. The two most important ligands are EGFR and TGF α , both of which are increased by mesothelial asbestos exposure. Inhibition of EGFR and vascular endothelial growth factor (VEGF) pathways by tyrosine kinase inhibitors⁷⁶ and inhibitors to VEGF production or VEGF receptors⁷⁷ will decrease or inhibit mesothelioma cell growth. VEGF production is increased by SV40 infection of mesothelioma cells.⁷⁸ Inhibitors of VEGF^{79,80} and EGFR pathways⁷⁶ in patients with mesothelioma are currently used in clinical studies.

Viral Activation of Mesothelioma Cells

SV40 is a double-stranded circular polyomavirus that contaminated polio vaccines in the United States, Canada, Europe, Asia, and Africa between 1955 and 1963. This virus has the potential, based on molecular, pathologic, and clinical evidence, to cause cancer.⁸¹ It has two major chromosomal regions, one of which harbors latent oncogenic potential. The early region encodes for SV40Tag (large tumor antigen), SV40tag (small tumor antigen), and 17 KT; the late region encodes for structural proteins of the virus.

It has been postulated that SV40 infection may increase the cellular production of growth factors, such as VEGF⁸² and HGF, through autocrine and paracrine mechanisms.⁷⁸ It may also protect cells from apoptosis by the ectopic production of telomerase, which prevents chromosomal shortening with successive cell division.⁸³

SV40Tag can bind to and inactivate the tumor suppressor genes *p53* and *Rb*, unleashing uncontrolled tumor growth. Small tumor antigen (SV40tag) may inhibit PP2A, leading to dephosphorylation of members of the MAPK family and deactivation of Wnt and ERK, which may lead to increased cellular transcription.⁸⁴

Despite the powerful putative oncologic attributes of SV40 virus, however, there is much debate in the literature as to the role of SV40 in cellular transformation; the oncologic potential of SV40 is very controversial and current opinion discounts its oncologic potential.^{85,86} The counterargument to the role of SV40 in inducing neoplasia in mesothelial cells is supported by the lack of viral particles identified within mesothelioma cells.⁸⁷ Further support for this counterargument is empirically derived from the knowledge that p14^{ARF} and p16^{INK4a} cause mesothelioma mutational changes, with upstream deactivation of *p53* and *Rb*, thus rendering SV40

inactivation of these tumor suppressor genes redundant and therefore obsolete.

Apoptotic Processes

Extracellular ligands of the caspase pathway, such as TNF, TNF-related apoptosis-inducing ligand (TRAIL), and Fas ligand, induce programmed cell death in normal cells. Intracellular mediators of apoptosis, including telomerase (see “[Viral Activation of Mesothelioma Cells](#)”) and proteins from the *bcl-2* family, which may have proapoptotic and antiapoptotic properties, are increased in mesothelioma patients. Protein expression from this family may have a diagnostic and prognostic role in clinical medicine.^{75,88} Proapoptotic Bcl-2 proteins induce apoptosis by increasing mitochondrial membrane permeability, in turn leading to caspase pathway activation. Antiapoptotic Bcl-xl expression is increased in mesothelioma. This can also be targeted by inhibitors of antisense oligonucleotides⁸⁹ or viral vector transfection of mesothelioma cells.⁹⁰

CLINICAL ASPECTS OF PLEURAL TUMORS

Pleural tumors are recognized by the characteristic radiographic appearance of a thickened pleural layer that contains fluid, solid tumor, or a combination of both. Patients may or may not have symptoms of chest pain or dyspnea consequent to lung restriction or compression. In rare cases, pleural tumors are associated with other symptoms, such as hypoglycemia or hypertrophic pulmonary osteoarthropathy. Radiographic evidence of pleural thickening in either symptomatic or asymptomatic patients is often the stimulus to initiate clinical studies to confirm the benign or malignant nature of the pathology or to redress, if possible, the underlying lung compression.

It is often difficult to distinguish benign from malignant pleural reactions ([Box 31-1](#)). As with other benign pleural conditions, the mesothelial cell also may release mediators such as cytokines, chemokines, oxidants, and proteases. These mediators may induce an exudative pleural reaction that gives rise to a proliferative hyperplasia of the mesothelial and submesothelial layers.^{1,35} This reaction can resemble a malignant process. Thus, pleural thickening can be attributable to multiple causes, ranging from benign inflammation to malignancy, as summarized in [Box 31-2](#).

Inflammatory Pleural Reactions

The pleura reacts to pleural injury either by development of a reactive mesothelial hyperplasia or organizing pleuritis (as opposed to atypical mesothelial hyperplasia, described later) or by the formation of nodular pleural plaques. Plaques are acellular deposits on the parietal pleura that often calcify. They are usually associated with asbestos exposure.^{91,92} These benign lesions are often multiple and occur bilaterally. Their presence raises the possibility of mesothelioma or lung cancer, either on presentation or in the future.

BOX 31-1 Benign Causes of Pleural Hyperplasia

- Pleural infections
- Radiation
- Surgery
- Trauma
- Intracavitary treatments (chemotherapy or sclerosing agents)
- Collagen vascular diseases
- Systemic immune diseases (systemic lupus erythematosus, rheumatoid arthritis, Sjögren syndrome, Wegener granulomatosis)
- Subpleural pulmonary abnormalities (infarction, infection, neoplasia)
- Pneumothorax
- Drug reactions (nitrofurantoin, bromocriptine, methysergide, procabazine)
- Pancreatitis, uremia
- Pneumoconiosis (asbestosis)

BOX 31-2 Causes of Pleural Masses

- Inflammatory pleural reactions
 - Reactive mesothelial hyperplasia or organizing pleuritis versus atypical mesothelial hyperplasia
 - Nodular pleural plaques
- Pulmonary tumors that may resemble pleural tumors
 - Inflammatory pseudotumor of the lung
- Benign pleural tumors
 - Solitary fibrous tumor
 - Lipomas and lipoblastomas
 - Adenomatous tumors
 - Calcifying fibrous tumors
 - Mesothelial cysts
 - Multicystic mesothelioma
 - Schwannoma
- Pleural tumors with low malignant potential
 - Desmoid tumors
 - Well-differentiated papillary mesothelioma
 - Pleural thymoma
- Primary malignant pleural tumors that may look like benign tumors
 - Malignant solitary fibrous tumor
 - Pleuropulmonary blastoma
 - Localized malignant mesothelioma
 - Vascular sarcoma
 - Liposarcoma
 - Pleuropulmonary synovial sarcoma
 - Askin tumor or primitive neuroectodermal tumor (PNET)
 - Desmoplastic small round cell tumor
- Malignant pleural tumors
 - Metastatic malignancies to the pleura
 - Malignant mesothelioma

Pulmonary Tumors That May Resemble Pleural Tumors

Inflammatory pseudotumor of the lung is a rare pulmonary tumor in adults, but it is the most common primary pulmonary tumor in children.⁹³ These tumors may be associated with a pleural thickening that responds to steroid therapy.⁹⁴

The specific histologic features of a *benign reactive mesothelial hyperplasia* that mimics malignancy include high cellularity, cytologic mitoses, necrosis, papillary excrescences, and entrapment of mesothelial cells in organizing pleuritis. Immunohistochemistry may be of limited help in differentiating benign from malignant pleural pathology. Its primary value may be in the demonstration of invasion by immunostaining of invasive cells. Invasion is a key marker for malignancy and must be differentiated pathologically from entrapment, pseudo-invasion, or sequestration.^{95,96}

Indeterminate lesions may appear on pleural biopsy as a proliferation of atypical mesothelial cells, either in a monolayer or piled up with cellular accumulations. These lesions may demonstrate increased cytologic atypia without evidence of true invasion; they may remain benign or degenerate into malignancy.^{95,97}

Benign Pleural Tumors

Benign pleural tumors comprise less than 5% of all pleural tumors. Far more commonly, they represent either metastatic cancer or a diffuse malignant pleural mesothelioma. These malignant tumors share common properties with benign pleural tumors, which can make it difficult to establish the diagnosis, particularly with small biopsies of minimal amounts of tissue. The common properties of benign and malignant pleural tumors are that both originate from, or metastasize to, mesothelial or submesothelial surfaces; both may recur after surgical removal; and both are difficult to identify with limited tissue biopsy material because of patterns of heterogeneous cellularity.⁹⁸

However, it is important to be able to distinguish a benign from a malignant pleural tumor, because the benign form confers excellent survival potential. Some benign tumors may recur after complete resection, and they may still be treated surgically with curative intent.

A radiograph of a patient with benign tumors of the pleura reveals a thickened parietal layer with underlying lung compression. Occasionally, these tumors have the appearance of lung invasion (particularly if they are visceral pleura based), as in the inverted fibroma form of solitary fibrous tumors. These pleural abnormalities are identified by a variable thickening of either the visceral or parietal pleura. This imposes a diagnostic dilemma because of the many possible causes of pleural masses in the differential diagnosis. Furthermore, fine-needle aspirates of these abnormalities are often unreliable for confirming a diagnosis as a benign pleural tumor.^{96,99-101}

From a clinical perspective, primary pleural tumors span a pathologic spectrum ranging from benign tumors, to benign tumors with some malignant features, to frankly malignant tumors. The most common pleural tumor (solitary fibrous tumor of the pleura) can occur in either a benign or a malignant form; they may also recur in either a benign or a malignant form.^{98,102}

Benign Pleural Tumors That May Remain Benign

Solitary Fibrous Tumors. The solitary fibrous tumor is the most common benign pleural tumor, and it is rare (by

2002, only 800 cases had been reported).⁹⁸ (In contrast, 3000 new cases of diffuse mesothelioma are diagnosed yearly in the United States.¹⁰³) This tumor arises from the submesothelial layer of the mesothelioma and it is usually solitary, although it may occur in multiple sites.^{104,105} It is associated with hypertrophic pulmonary osteoarthropathy in up to 22% of cases, and with severe hypoglycemia in 3% to 4% of cases.¹⁰⁶ The latter syndrome (Doege-Potter syndrome) is attributable to tumor-derived growth factor (insulin-like growth factor II).¹⁰⁷

These tumors are often (>80%) attached to the visceral pleura, and they are often pedunculated (80%). In the remaining 20% of cases, they originate from the parietal pleura on the diaphragmatic or mediastinal surface, and parietal-based tumors are more likely to be sessile than pedunculated.¹⁰⁵ Pedunculated tumors have a 2% recurrence rate, whereas sessile tumors have an 8% recurrence rate.⁹⁸

Because the solitary fibrous tumor is often pedunculated, it is amenable to resection by video-assisted thoracic surgery (VATS). However, resection should be complete and without tumor disruption to prevent tumor recurrence from either incomplete resection or microscopic seeding of the resected bed. It is important to remove not only the tumor but also the stalk with a 1-cm base of underlying lung. If the tumor is too large for VATS surgery, a thoracotomy may be required.^{98,100} Tumors originating from the parietal pleura require at least a partial pleurectomy with the tumor resection. Occasionally, chest wall resection along with tumor removal is required if there is concern about recurrence or invasion from possible malignant transformation.

Sessile lesions larger than 5 cm should probably be removed by thoracotomy to prevent recurrences.¹⁰⁰ These tumors may appear to invade the lung if visceral growth (inverted fibroma) is seen, so lung resection may be required. Peritumoral adhesions, in which microscopic tumor deposits may hide, are common (60%), so a wide resection is needed. This can include lung, diaphragm, chest wall, and pericardium with frozen section determination that all margins are free of tumor at resection.¹⁰⁰ Recurrent tumors may be multifocal and may undergo malignant transformation.¹⁰² Because histologic characteristics do not always predict the potential for recurrence, long-term follow-up is necessary.

Lipomas and Lipoblastomas. Chest wall lipoma is a common incidental finding, occurring in 0.1% of all computed tomography (CT) scans of the chest.¹⁰⁸ Lipoblastoma is a tumor of embryonic white fat that typically occurs in infancy or early childhood.¹⁰⁹ Both lipomas and lipoblastomas are benign and are best treated by surgical excision of the involved area.

Adenomatoid Tumors. Adenomatoid tumors are very rare incidental findings appearing as solitary circumscribed lesions on either the parietal or visceral pleura. They are usually identified at the time of pulmonary resection for unrelated pathology. They occur more commonly in other sites (most commonly the genital tract), and resection is performed to exclude other malignant pleural tumors.¹¹⁰

Calcifying Fibrous Tumors. Calcifying fibrous tumors are rare and are characterized by dense collagenous tissue with psammoma bodies containing dystrophic calcifications. They commonly occur in subcutaneous tissue or in deep soft tissue, but rarely in the pleura (there have been nine reports of this tumor since the initial report in 1996). They can occur as solitary tumors or in multiple sites; calcifications are typically not seen on plain chest films but are seen on a CT scan.¹¹¹⁻¹¹⁸

Simple Mesothelial Cysts. The pleura is an uncommon site for the development of a mesothelial cyst, which is thought to arise from persistence of the ventral pericardial recess after embryonic development. These lesions often occur in the anterior right cardiophrenic angle. The cysts that retain a connection to the pericardium are called pleuropericardial cysts, and if the neck to the pericardium is pinched off, they are classified as mesothelial cysts. They can be treated with surveillance unless symptoms develop, and then they can be treated by either aspiration or excision by VATS.^{119,120}

Multicystic Mesothelial Cysts. Multicystic inclusion cysts (multicystic mesothelioma or multilocular inclusion cysts) appear as multilocular fluid-filled cysts spread along the serosal surface of the pleura. These are extremely rare abnormalities occurring in asymptomatic individuals, and their removal to exclude other pathologies can be accomplished by VATS surgery.¹²¹

Schwannoma. Schwannomas are peripheral nerve sheath tumors that may occur spontaneously or after radiotherapy.¹²² They may arise in paraspinal intrathoracic locations and may mimic loculated fibrous deposits or localized pleural tumors. The key to the removal of this tumor is to exclude the possibility of spinal extension to prevent paraplegia from compressive spinal cord hematoma formation caused by bleeding into the peritumoral area.

Pleural Tumors with Low Malignant Potential

Well-Differentiated Papillary Mesothelioma

Well-differentiated papillary mesothelioma typically occurs with a diffuse nodular growth over the mesothelial surface, although there is only superficial invasion without deep invasion except in recurrent or long-standing lesions. Diagnosing this lesion is difficult because it looks similar to invasive mesothelioma (diffuse malignant mesothelioma) on small biopsy specimens. These lesions have an indolent course in the absence of invasive features, and in most cases they do not shorten life expectancy.¹²³

Desmoid Tumors

Desmoid tumors, which usually arise from facial or musculoaponeurotic structures, commonly arise from the chest wall with visceral invasion, although pleural desmoid tumors have been documented.^{124,125} They may be

associated with aggressive fibromatosis via the APC tumor suppressor gene or the β -catenin oncogene acting through the main intracellular effector pathway of the Wntless/Wnt signaling pathway.^{126,127}

The treatment of these tumors requires complete resection with negative margins,^{124,125,128} although recurrence may occur even with negative margins.¹²⁵ However, surgical resection of recurrences has excellent potential for long-term cure.¹²⁸

Pleural Thymoma

Pleural thymomas may arise from the pleura and can appear in either a localized or diffuse form. They probably arise from ectopic thymic tissue in the pleura, although this occurrence is rare (only 15 cases reported by 2002).¹²⁹ The localized form can be surgically removed for cure; the diffuse form may require radiotherapy.^{123,130}

Primary Malignant Pleural Tumors That May Look Like Benign Tumors

Malignant Solitary Fibrous Tumor

Patients with this tumor, which arises from mesenchymal cells in the submesothelial layer with malignant degeneration, are more likely to have larger, symptomatic, sessile tumors than their benign pedunculated counterparts.^{98,99,131} Visceral-based tumors are less likely to be malignant,¹³² and they are more often pedunculated than the parietal-based tumors.^{98,100} Malignancy is also more often associated with CT heterogeneity of these tumors, pleural effusions, chest wall invasion, and positivity with positron emission tomography (PET).^{99,100} CT-guided aspiration to determine malignancy is notoriously inaccurate,^{99,100} possibly because the tumor heterogeneity results in sampling error.

After tumor removal, malignancy is determined on the basis of cellularity and high mitotic counts, nuclear pleomorphism, presence of areas of tumor necrosis, and stromal or vascular invasion. Malignancy occurs in approximately 37% of case series of solitary fibrous tumors (range, 7% to 60%).¹⁰⁰ Recurrence is usually local and strongly associated with malignancy. It occurs with the following frequencies: benign pedunculated, 2%; benign sessile, 8%; malignant pedunculated, 14%; malignant sessile, 63%.⁹⁸

Benign tumors may also recur as malignant tumors,^{102,133} indicating the need for long-term follow-up. All tumors and recurrences are best treated with aggressive surgical resection or extended resection if necessary.^{98,100} The value of adjuvant therapy for malignant tumors is debated.^{98,100,131}

Pleuropulmonary Blastoma

Pleuropulmonary blastoma (PPB) arises from either the lung or the visceral pleural lining and affects children younger than 6 years. This tumor is unique in its progression from a cystic stage (type I, multilocular cystic tumors), to a more aggressive stage (type II, mixed cystic

and solid tumors), and finally to the most aggressive stage (type III, solid tumor). Age correlates with the type of PPB: younger patients (median age, 9 months) tend to have type I, whereas older patients (median age, 42 months) tend to have type III.¹³⁴ There is strong evidence for sequential progression of tumor from type I to type II to type III, and recurrences after surgical removal of type I tumors always arise as type II or III tumors, with a low salvage rate.¹³⁵ The survival rate after successful resection of type I tumors is 85% to 90%, but it drops to 60% for type II and 45% for type III tumors.^{134,136} Important treatment points concerning this tumor are a thorough histologic review of any multiloculated pediatric lung cyst, continued CT surveillance of these patients, and consideration of adjuvant chemotherapy for resected type I tumors.¹³⁶

Localized Malignant Mesothelioma

Localized malignant mesothelioma is a rare tumor: by 2007, only 46 cases had been reported in the English literature.¹³⁷ By all histologic, immunohistochemical, and ultrastructural criteria, these tumors are similar to diffuse malignant mesothelioma.¹³⁸ Their diagnosis depends on the following factors: (1) radiologic, surgical, or pathologic evidence of a localized serosal or subserosal tumor mass without evidence of diffuse serosal spread, and (2) a microscopic pattern identical to that of diffuse malignant mesothelioma.¹³⁹ The small number of case series in the literature do not show it to have a strong association with asbestos exposure.¹³⁷ Recurrence after surgical resection may occur either locally or with distant metastases, although only rarely does diffuse pleural spread occur with recurrence, and, in contradistinction to diffuse malignant mesothelioma, many cases are cured by surgical excision.^{137,138}

Vascular Sarcoma

The two types of pleural vascular sarcomas are epithelioid hemangioendothelioma and angiosarcoma, and the former has a lesser histologic grade. Both may demonstrate smooth to nodular pleural thickening resembling diffuse malignant mesothelioma. Differentiating these vascular sarcomas from mesothelioma can be done by immunostaining for vascular markers (CD34, CD31, factor VIII).^{123,138} Both types are very aggressive, and the outcome is often poor despite aggressive treatment.¹⁴⁰

Liposarcoma

Liposarcomas are rare (15 cases in the English literature to 2007). They are thought to be derived from residual nests of primitive mesenchymal cells in the pleural cavity. Surgical resection with consideration of postoperative chemotherapy is the recommended treatment for patients with these tumors.^{123,141}

Pleuropulmonary Synovial Sarcoma

Pleuropulmonary synovial sarcoma is a distinct histologic subtype of sarcoma that is identified as a mesenchymal

spindle cell tumor with a specific chromosomal translocation of t(X;18)(p11.2;q11.2). The name is a misnomer—these tumors have no relationship to synovial tissue. They are thought to derive from totipotent mesenchymal cells with epithelial differentiation. Most of these tumors are large and pleural based with heterogeneous areas of necrosis or hemorrhage; it is important to differentiate these rare primary pleural tumors from the more frequently seen metastatic synovial sarcoma to the lungs.¹⁴² Only a few anecdotal reports about treatment of this tumor appear in the literature. Treatment includes surgical resection and adjuvant therapy. Chemotherapy or radiotherapy may be added to the treatment regimen, based on soft tissue synovial sarcoma experiences and anecdotes of poor results with this tumor in thoracic locations.^{142,143}

Askin Tumor or Primitive Neuroectodermal Tumor (PNET)

The Askin tumor, or primitive neuroectodermal tumor (PNET), is a soft tissue tumor that appears either as a single lesion or as multiple pleural nodules in children and young adults. It is classified as a member of the Ewing sarcoma family because the chromosomal aberration t(11;22)(q24;q12) is peculiar to both tumors. However, PNET originates from soft tissue, whereas Ewing sarcoma is a tumor of bone. Extrapolated data from a single-center report of treatment of PNET¹⁴⁴ or the combined results of both tumors¹⁴⁵ suggest consideration of neoadjuvant chemotherapy, surgical resection, and adjuvant chemoradiotherapy.

Desmoplastic Small Round Cell Tumor

The desmoplastic small round cell tumor is a rare aggressive malignancy that affects adolescents and young men; fewer than 10 thoracic cases have been described.^{95,146,147} These tumors may remain localized, but more commonly they involve the pleura diffusely. They have a unique expression of epithelial, muscle, and neural markers, with a characteristic fusion protein as a result of gene fusion transcript between the Ewing sarcoma gene on chromosome 22 and the Wilms tumor gene on chromosome 11, t(11;22)(p13;q22).^{123,138} The prognosis is poor, as it is in patients with abdominal presentations of this tumor.

Malignant Pleural Tumors

Metastatic Malignant Tumors

Metastatic tumors to the pleura are common (>150,000 new cases each year in the United States); the tumor of origin in 75% of cases is lung, breast, or lymphoma, with minor contributions from ovary and stomach. In 5% to 10% of cases, the primary site is unknown.^{148,149} Patients with metastatic pleural tumors often present with symptoms from a pleural effusion because of lymphatic obstruction of pleural fluid or because of increased capillary permeability in response to tumor invasion, either by direct local tumor extension or by tumors (ovary, breast) with a predilection for serosal invasion by

a hematogenous route.¹⁵⁰ Examples of secondary pleural effusions (paramalignant effusions) caused by tumor-associated effusions without direct neoplastic involvement of serosal surfaces are chylothoraces, proximal bronchus obstruction with postobstructive atelectasis, and effusions resulting from cancer cachexia.¹⁴⁹ Metastatic tumors to serosal surfaces resulting in effusions develop site-based cellular differences between effusion tumor cells and cells from the primary or other metastatic sites. Such differences include upregulation of matrix metalloprotein (MMP)-2, and other adhesion molecules (cadherins, integrins), reduced reliance on ERK-driven pathways or chemokines for proliferation, and apoptosis resistance despite increased death receptor expression and in accordance with increased inhibitors of apoptosis proteins.¹⁵⁰

Determination of malignancy by cytologic examination of pleural effusions ranges from 62% to 90% of patients with malignant pleural effusions; increased test sensitivity can be achieved by repeated thoracenteses, electro-chemiluminescence immunoassay, genetic analysis by microsatellite analysis, DNA methylation, determination of aneuploidy, and immunocytochemistry by a variety of techniques.¹⁵¹ Gene expression tests such as EGFR mutation and receptor analysis can be useful both for tumor differentiation and for response to treatment.¹⁵² Malignant pleural effusions can be managed by a variety of techniques with a goal of creating a pleural symphysis. Such techniques range from a variety of catheter drainage procedures with the option of several different sclerosing agents, to pleuroperitoneal shunting or a surgical pleurectomy and decortication.^{148,149,151,153,154}

Restraint with respect to aggressive surgical strategies is appropriate, because, apart from breast cancer, the median survival from malignant pleural effusions is less than 6 months.¹⁵⁵ Massive effusions fare worse than lesser effusions.¹⁵⁶

Diffuse Malignant Pleural Mesothelioma

Diffuse malignant pleural mesothelioma (MPM) is the most common primary pleural tumor, but it occurs less commonly than distant malignancy with metastatic involvement of the pleural surfaces.^{151,154} An aggressive tumor, MPM arises from the mesothelial cells of the pleura. Although it can spread systemically, it grows preferentially over serosal surfaces, penetrating the interlobar fissure and eventually encasing the lung. The disease can occur at any site where mesothelial cells de-differentiate from mesenchymal cells, including the peritoneum, pericardium, tunica vaginalis of the testes, and ovary. The pleura, however, is the most common site of involvement of MPM. In the United States, there are approximately 2000 to 3000 new cases each year. Annual mortality rates in Britain and the rest of the world are projected to continue to rise, peaking in 2020.^{24,157}

Mesothelioma has several histologic subtypes (Fig. 31-1). Epithelial mesothelioma is the most prevalent type, followed by mixed/biphasic, sarcomatous, and, rarely, desmoplastic types.¹⁵⁸ In a study of 1517 cases, the epithelial cell type was found in 61.5% of the specimens,

followed by the biphasic type in 22%, and the sarcomatous type in 16.4%.¹⁵⁹ Unusual histologic subtypes of mesothelioma include tubular, capillary, solid, large or giant cell, small cell, clear cell, signet cell, glandular, microcystic, myxoid, and adenoid cystic.¹⁶⁰

Clinical Presentation. In early-stage disease, the symptoms are often subtle and the disease may be identified only because of a serendipitous finding on a chest radiograph performed for other complaints. The most common presenting symptom associated with mesothelioma is dyspnea (80%) caused by restrictive compression of the affected lung. Cough (69%) and weight loss (40%) may also occur; fatigue and weakness are generally later symptoms.¹⁶¹ Mesothelioma is usually not associated with pleuritic chest pain,¹⁶² which may suggest chest wall invasion. If invasion is confined to a localized area of the chest wall, this may still permit surgical resection. If diffuse, it may indicate nonresectable disease.

Physical examination may reveal a spectrum of signs from minimal disease to an absence of breath sounds suggestive of a unilateral pleural reaction in the involved hemithorax.

The chest radiographs typically reveal a large pleural opacity; this may also be associated with evidence of pleural-based masses (identified as nodular or irregular pleural thickening).¹⁶³ In advanced cases, mediastinal compression or intercostal narrowing can be seen on the chest radiograph; rib erosion or periosteal reaction is indicative of chest wall invasion. The chest CT scan is more accurate than plain films for identifying the extent of disease, the potential for lung compression or invasion of local structures, and metastatic spread to the mediastinal nodes. Magnetic resonance imaging (MRI) is generally superior to CT for evaluating diaphragmatic or mediastinal invasion. However, neither mode is 100% accurate, and operative exploration may be required to determine resectability.

Recently, PET-CT imaging has been shown to increase the accuracy of MPM staging¹⁶⁴ and to indicate extrathoracic occult disease. PET-CT scans are 91% sensitive and 100% specific in differentiating benign from malignant pleural disease.¹⁶⁵

Histologic identification of the pleural abnormality is required to determine the malignant nature of the pleural mass, as well as to identify the tumor type and subtype. Often, thoracentesis is the initial step for symptomatic relief of a pleural effusion and for diagnosis. However, the cytologic yield from this type of sample is relatively poor, only 62%.¹⁶⁶ The yield from pleural needle biopsy is somewhat better, at 86%.¹⁶⁷ VATS has been shown to be an effective method of enhancing the diagnosis of MPM, and it provides specimens from selected biopsy areas of parietal, visceral, and diaphragmatic pleura.¹⁶⁸ Extensive sampling is often still needed, but collection in this fashion is diagnostic in 98% of patients.

The visual manifestations of mesothelioma as seen either at open thoracotomy or by VATS can be described as localized mass lesions (rarest form), pleural studding and small plaques (discontinuous), pleural masses with variable confluence, and lung encasement with tumor invasion of chest wall and lung.^{139,169}

FIGURE 31-1 ■ The pathologic classification of mesothelioma reveals three histologic patterns. Diffuse malignant mesothelioma is categorized as epithelioid, sarcomatoid, or biphasic (mixed) epithelioid mesothelioma. **A**, Epithelioid subtype (hematoxylin & eosin [H&E], ×400). In this typical photomicrograph of epithelioid mesothelioma, the cells are arranged in a tubular pattern. **B**, Immunostaining pattern of malignant mesothelioma, epithelioid subtype. Note the more solid pattern of cells highlighted with cytokeratin immunostaining (AE1/AE3, ×400). The photomicrograph also demonstrates invasion of tumor cells into the chest wall adipose tissue. **C**, Sarcomatoid subtype (H&E, ×400). Spindle-shaped cells are arranged in sheets or fascicles that form nonspecific architectural patterns resembling those seen in the various sarcomas. **D**, The biphasic or mixed subtype is characterized by the presence of both epithelioid and sarcomatoid components (H&E, ×400). (Courtesy Lucian Chirieac, MD, Brigham and Women's Hospital, Boston.)

Tissue samples that are removed for histologic evaluation must be carefully evaluated to differentiate between benign proliferative mesothelial processes and malignant mesothelioma. It is also difficult to determine differences between epithelial mesothelioma, sarcomatoid mesothelioma, and sarcoma. Definite stromal invasion is the most reliable indicator of malignancy in both epithelial and spindle cell neoplasms.¹⁷⁰ Densely packed mesothelial cells in the pleural space are consistent with a benign disease process, but if they are found in the stroma, it is more suggestive of malignant mesothelioma. The three histologic subtypes of malignant mesothelioma are classified according to the relative proportions of epithelial and spindle cells. These include epithelial, sarcomatoid (spindle), and mixed (see Fig. 30-1). The epithelial subtype accounts for more than 50% of tumors and needs to be carefully differentiated from adenocarcinoma.^{171,172} Electron microscopy may aid in this differentiation. The basement membrane underlying adenocarcinoma cells

has a more complete structure than that which underlies mesothelioma cells.¹⁷³ Mucopolysaccharide stains (i.e., periodic acid–Schiff, Mayer mucicarmine) are strongly positive in adenocarcinomas and usually absent in mesotheliomas. The presence of hyaluronic acid strongly supports the diagnosis of mesothelioma. Epithelial mesotheliomas are further characterized not only by their architectural pattern, including tubular, tubulopapillary, papillary, solid, or microcystic types, but also on the basis of their cytologic features, including small cell, large cell, deciduoid, or clear cell types.¹⁷⁴ The sarcomatoid subtype accounts for 15% to 20% of tumors and must be distinguished from sarcomas.^{175,176}

Although no single immunohistochemical marker is sufficiently sensitive and specific to differentiate mesothelioma from adenocarcinoma, sarcoma, or reactive mesothelial hyperplasia, a panel of markers is currently used to aid in this distinction.¹⁷⁷ The antibody calretinin demonstrates good specificity for mesothelial cells,

whereas carcinoembryonic antigen (CEA) is highly specific for adenocarcinoma.¹⁷⁸ Low-molecular-weight cytokeratin is a general marker of mesothelioma, whereas the high-molecular-weight cytokeratins favor epithelial mesothelioma in particular.¹⁷⁹ Thyroid transcription factor-1 (TTF-1) and E-cadherin stains also help differentiate mesothelioma from adenocarcinoma: mesothelioma specimens are negative for TTF-1 and adenocarcinomas are positive for E-cadherin.¹⁸⁰ These two markers serve as the frontline immunohistochemical staining for mesothelioma, which can be followed by a secondary panel of antibodies including BerEP4, Leu M1, calretinin, cytokeratin 5/6, and N-cadherin, if necessary. Gene expression techniques involving microarray RNA profiling may be helpful to distinguish between mesothelioma and adenocarcinoma.¹⁸¹ This work uses gene product ratios and is a novel approach to diagnosing MPM, with an accuracy of between 95% and 99%.

After histologic confirmation of mesothelioma, the staging of this disease becomes central to determining the best therapy for a particular patient. Staging is equally important in assessing the effectiveness of a new therapy, and it helps to ensure that proper comparisons are made between treatment groups. When study results are reported or compared, it is important to distinguish between clinical and pathologic staging. Unfortunately, there is lack of consensus for a single mesothelioma staging system, and several staging systems are in use today. These include the Butchart staging system,¹⁸² the tumor-nodes-metastasis (TNM) staging system set forth by the Union for International Cancer Control (UICC),¹⁸³ the International Mesothelioma Interest Group (IMIG) staging system based on TNM status,¹⁸⁴ and the Brigham and Women's Hospital/Dana-Farber Cancer Institute staging system.¹⁸⁵

The Butchart classification system for MPM, described in 1976, was the first to be introduced and is quite simple, but it fails to provide any prognostic information because anything beyond stage I is considered unresectable.¹⁸²

The UICC staging system, described in 1990, was based on the TNM cancer staging system used for non-small cell lung cancer (NSCLC).¹⁸³ Because of the nature of mesothelioma tumor growth in the pleural space, the T variable as it is described in terms of NSCLC is not always applicable in patients with mesothelioma. Furthermore, although the N nodal description is the same as for NSCLC, in mesothelioma it is often difficult to evaluate nodal stations when the pleural space is completely filled with tumor or effusion. Because of the short overall survival in mesothelioma, patients often do not live long enough for metastatic disease (M) to be found. Once again, this staging system falls short clinically because it fails to correlate with patient survival and prognosis.

In 1994, another staging system was proposed by the IMIG (Box 31-3). This classification system attempts to account for the unique features of mesothelioma while using the accepted T and N status indicators. In this system, T1a tumors involve the ipsilateral parietal pleura with or without diaphragmatic involvement, and T1b tumors involve the visceral pleura. T2 disease invades the

lung parenchyma, so that lung resection would be necessary for complete removal of tumor. These tumors are associated with a pleural effusion. T3 tumors are locally advanced but are still amenable to resection in that there is involvement of endothoracic fascia, mediastinal fat, localized chest wall, or pericardium. T4 disease is technically unresectable and involves invasion of tumor into the chest wall, through the diaphragm into the peritoneum, or into the contralateral pleura, mediastinal organs, spine, internal pericardial surface, or myocardium. Staging of nodal involvement in the IMIG system is similar to NSCLC staging. Stages Ia and Ib correlate with T1aN0 and T1bN0, respectively. Stage II includes T2N0 tumors. Stage III is any T3 or any N1 or N2, and stage IV involves any T4, N3, or M1 disease.

The Brigham and Women's Hospital/Dana-Farber Cancer Institute staging system is simpler than a TNM-based system (Table 31-1) and offers better prognostic value for patients treated with different modalities. Stage I disease is resectable without lymph node involvement. Stage II tumors are also confined to the pleural envelope, but they include positive lymph node (N0 or N1) involvement. Stage III disease is unresectable, with locally aggressive tumors invading the mediastinum, diaphragm, or chest wall with or without extrathoracic or contralateral (N2 or N3) lymph node involvement. Stage IV tumors are associated with extrathoracic metastases. This system stratifies patients according to survival and accounts for resectability, tumor histology, and nodal status. The validity of this staging system has been confirmed in an analysis of a series of 120 patients.¹⁸⁶

Prognosis. MPM is a rare but highly aggressive tumor of the pleura that has defied a standard approach to treatment. Without treatment, the median survival ranges from 4 to 12 months.¹⁸⁷⁻¹⁸⁹ Recommended treatment strategies are based on the same principles applied to other solid tumors and include chemotherapy, radiation, surgery, and combinations thereof. Assessment of response to treatment can be measured according to certain criteria.¹⁹⁰ However, mesothelioma tumors have a unique growth pattern with a preference for serosal spreading, which makes the application of conventional response criteria sometimes difficult.¹⁹¹ A modification of these criteria for tumor response correlates with survival and lung function and can be used to measure outcome

TABLE 31-1 Brigham Women's Hospital Revised Staging System

I	Disease confined to the capsule of the parietal pleura: ipsilateral pleura, lung, pericardium, diaphragm, or chest wall disease limited to previous biopsy sites
II	All stage I with positive intrathoracic (N0, N1) lymph nodes
III	Local extension of disease into chest wall, mediastinum, or heart, or through diaphragm or peritoneum, with or without extrathoracic or contralateral (N2, N3) lymph node involvement
IV	Distant metastatic disease

BOX 31-3 International Mesothelioma Interest Group (IMIG) Staging System**T PRIMARY TUMOR AND EXTENT**

- T1**
- Tumor limited to ipsilateral parietal pleura, including mediastinal and diaphragmatic pleura; no involvement of the visceral pleura
 - Tumor involving the ipsilateral parietal pleura, including mediastinal and diaphragmatic pleura; scattered foci or tumor also involving the visceral pleura
- T2** Tumor involving each of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic pleura); scattered foci or tumor also involving the visceral pleura
Involvement of diaphragmatic muscle
Confluent visceral pleura (including the fissures) or extension of tumor from visceral pleura into the underlying pulmonary parenchyma
- T3** Locally advanced but potentially resectable tumor; tumor involving all the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following features:
Involvement of the endothoracic fascia
Extension into mediastinal fat
Solitary, complete resectable focus or tumor extending into the soft tissues of the chest wall
Nontransmural involvement of the pericardium
- T4** Locally advanced, technically nonresectable tumor; tumor involving all the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following features:
Diffuse extension or multifocal mass of tumor in the chest wall, with or without associated rib destruction
Direct transdiaphragmatic extension of the tumor to the peritoneum

Direct extension of tumor to the contralateral pleura
Direct extension of tumor to one or more mediastinal organs
Direct extension of tumor into the spine
Tumor extending through the internal surface of the pericardium with or without a pericardial effusion or tumor involving the myocardium

N LYMPH NODES

- Nx** Regional lymph nodes cannot be assessed
N0 No regional lymph node metastases
N1 Metastases in ipsilateral bronchopulmonary or hilar lymph nodes
N2 Metastases in the subcarinal or the ipsilateral mediastinal lymph nodes, including the ipsilateral internal mammary nodes
N3 Metastases in contralateral mediastinal, contralateral internal mammary, ipsilateral, or contralateral supraclavicular scalene lymph nodes

M METASTASES

- Mx** Presence of distant metastases cannot be assessed
M0 No (known) metastasis
M1 Distant metastasis present

STAGE GROUPING

- I**
- T1aN0M0
 - T1bN0M0
- II** T2N0M0
III Any T3M0, any N1M0, any N2M0
IV Any T4, any N3, any M1

in mesothelioma treatments.¹⁹² In addition to tumor stage, several independent prognostic variables are important and have been defined in two scoring systems.^{193,194} These include age, performance status, and histologic subtype. Less important variables include chest pain, dyspnea, presence of pleural effusion, asbestos exposure, weight loss, anemia, leukocytosis, thrombocytosis (platelet count > 400,000/ μ L), and elevated lactate dehydrogenase (>500 IU/liter). The prognostic value of these scoring systems was confirmed in a retrospective review of an independent cohort of patients.¹⁹⁵ Tumors with epithelial histology carry a better prognosis.¹⁹⁶

Treatment. To date, there are no evidence-based consensus guidelines on the management of MPM. Because of its rare incidence, there are no randomized controlled trials that compare different surgical approaches with one another or that compare surgery to alternative treatments. The cumulative evidence in the literature lies in retrospective case series reports and prospective non-controlled studies. These data are further confounded by the changing classification and staging systems for mesothelioma.

Radiation Therapy. Mesothelioma cells have a modest sensitivity to radiation, less sensitive than small cell lung cancer but more sensitive than NSCLC.¹⁹⁷ Effective

treatment with an intact lung is largely limited by the collateral damage associated with the vital organs in the necessary radiation field.¹⁹⁸ It is difficult to assess the value of radiation therapy because no large study has compared radiation therapy to no treatment at all. In a small series of 23 patients reported by Ball and Cruickshank, those patients who received less than 40 Gy did not have effective palliation, whereas those receiving higher dosages were better palliated.¹⁹⁹

Radiation therapy has been shown to be effective in the prevention of local recurrence after thoracentesis or thoracoscopic biopsy.²⁰⁰ However, radiation is usually ineffective in controlling disease after partial surgical resections. Dosages must be limited to 20 Gy because of toxicity to the remaining lung. When a patient can undergo extrapleural pneumonectomy (EPP), adjuvant radiation can help reduce local recurrence, which arises in the ipsilateral hemithorax in more than 60% of cases. In one nonrandomized study, which did not reach statistical significance, 31% of patients treated with radiation after EPP had local recurrence, as opposed to 45% of patients not treated with adjuvant radiation.²⁰⁰ Those patients with negative margins did not show any decrease in local recurrence after postoperative radiation, whereas postoperative radiation was found to possibly benefit those with positive resection margins. External beam

radiation therapy, previously based on chest radiographs, has evolved to include intensity-modulated regimens based on three-dimensional field planning.²⁰¹ With careful intraoperative marking by the surgeon and postoperative planning by the radiation oncologist, intensity-modulated radiation beams maximize targeting of the tumor bed and avoid toxicity to surrounding vital structures.²⁰²

Chemotherapy. Mesothelioma is relatively chemoresistant, with response rates to single agents less than 20% and no effect on overall survival. The antimetabolites, anthracyclines, and platinum compounds seem to be the most active in mesothelioma. Methotrexate showed a 37% response rate in a phase II trial of 63 patients.²⁰³ However, toxicity was seen in 58% of patients. Detorubicin showed a greater response than doxorubicin in 35 patients, where a response rate of 26% was found.²⁰⁴ Cisplatin was demonstrated to have a 14% response rate in a Southwest Oncology Group study.²⁰⁵ At a higher dosing schedule, a 36% response rate was seen.²⁰⁶ However, there were significant side effects, and these prompted discontinuation in 34% of patients because of toxicity. Carboplatin showed a similar response rate of 11% and is somewhat better tolerated than cisplatin.²⁰⁴ Vinorelbine also has single-agent activity against mesothelioma, with a low incidence of serious side effects.²⁰⁷ Partial response with 50% reduction in tumor thickness was seen in 24% of patients, whereas 55% had stable disease (neither 25% increase nor 50% decrease in tumor thickness). Gemcitabine has limited activity when used alone.²⁰⁸ Pemetrexed has shown some encouraging results in single-agent therapy in 64 patients, where 14% experienced a partial response.²⁰⁹

Response rates are increased for combination therapies compared with single-agent treatments.²¹⁰ Therefore, single-agent treatment has given way to combination regimens. The results reported by Vogelzang and colleagues showed superior survival time, time to progression, and response rates for patients treated with pemetrexed plus cisplatin versus cisplatin alone.²¹¹ This was a randomized, multicenter, phase III trial in 456 patients. Epithelial histology dominated in more than two thirds of the patients, and stage III or IV disease was seen in 78% of cases. Median survival time was 12.1 months in the combined group versus 9.3 months for cisplatin alone, with response rates of 41.3% versus 16.7%, respectively. This combination is now generally accepted as the standard treatment for patients with mesothelioma,²¹² and further investigations into second-line chemotherapy regimens have begun.²¹³

Surgery. Patients must be suitable surgical candidates for thoracotomy before being considered for pleurectomy/decortication (P/D) or EPP. Age and functional status are the first markers to assess. There is no upper age limit; however, caution is required for patients older than 70 years or with a Karnofsky performance status of less than 70. Cardiopulmonary function is closely studied: a preoperative forced expiratory volume in 1 second (FEV₁) of less than 2 liters, or a predicted postoperative FEV₁ of less than 0.8 liters requires more intensive pulmonary investigation. A marginal preoperative FEV₁ warrants a quantitative radionuclide perfusion scan to predict the

postoperative pulmonary capacity.²¹⁴ Echocardiography provides valuable information, with its ability to assess cardiac function, wall motion abnormalities, valvular disease, and particularly pulmonary artery pressure. If required for further assessment, right heart catheterization may be performed. Left and right ventricular function must be preserved (>45%). Pulmonary hypertension (>45 mm Hg) is a contraindication to EPP.

CT and MRI are used to define the anatomic extent of the tumor and mediastinal or chest wall invasion, and to rule out abdominal extension of disease. CT-PET scanning and cervical mediastinoscopy provide additional staging for extrathoracic disease and lymph node involvement. Metastatic mediastinal node disease confirmed at mediastinoscopy is treated with neoadjuvant chemotherapy in an attempt to downstage the tumor, followed by restaging. The primary goal of surgery is to remove all gross visible tumor (macroscopic complete resection). The eligibility criteria for EPP are listed in [Box 31-4](#).^{17,32,82,182,215-219} Patients who do not meet these criteria may still be candidates for pleurectomy.

Extrapleural pneumonectomy: With routine hemodynamic monitoring, an epidural and a double-lumen endotracheal tube in position, a posterolateral thoracotomy is made. The incision begins midway between the posterior scapula and the spine and extends under the scapular tip along the course of the sixth rib to the costochondral junction.²²⁰ The latissimus and serratus muscles are divided. In general, any prior thoracoscopy port sites or incisions are excised and incorporated into the thoracotomy incision when feasible. The sixth rib is carefully identified and removed from just anterior to the paraspinous ligament posteriorly to the costochondral junction anteriorly. This sets up the start of the extrapleural dissection plane, which is established next. The fused pleura is dissected away from the chest wall until there is room to insert a retractor. Then, the dissection proceeds in an organized manner, packing off any dissected planes to tamponade bleeding during mobilization elsewhere. Blunt dissection using a sponge stick or a finger complements sharp dissection with scissors. Careful attention is given to the subclavian vessels superiorly; the contralateral pleural space and internal thoracic vessels medially;

BOX 31-4 Eligibility Criteria for Extrapleural Pneumonectomy

- Karnofsky performance > 70
- Renal function: creatinine < 2
- Liver function: AST < 80 IU/L; total bilirubin < 1.9 mg/dL; PT < 15 sec
- Pulmonary function: postoperative FEV₁ > 0.8 L, as calculated from PFTs and quantitative $\dot{V}/\dot{Q}$ scans
- Cardiac function: normal electrocardiogram and echocardiogram (EF > 45%)
- Extent of disease: limited to ipsilateral hemithorax, with no transdiaphragmatic, transpericardial, or extensive chest wall involvement

AST, Aspartate aminotransferase; EF, ejection fraction; FEV₁, forced expiratory volume in 1 sec; PFTs, pulmonary function tests; PT, prothrombin time; $\dot{V}/\dot{Q}$, lung ventilation/perfusion quotient.

and the azygos vein, superior vena cava, and esophagus (right side) and aorta, intercostal arteries, and esophagus (left side) posteriorly. Continuous reorientation helps avoid inadvertent injury, as does palpation of a properly positioned nasogastric tube.

At this point, a determination is made as to the resectability of the tumor. Once this has been confirmed, the diaphragm is dissected at the anterior border with the chest wall and pericardium. The diaphragm is avulsed from the chest wall by careful manual traction, as opposed to sharp dissection, which can actually lead to more bleeding. Care must be taken to ensure removal of all gross tumor, but it is necessary to leave a rim of the diaphragmatic crus intact for later patch reconstruction. The peritoneum is left intact if at all possible. Next, the pericardium is opened caudally. It is incised anteromedially toward the phrenic nerve and the hilar vessels. The pulmonary veins are divided intrapericardially. The pulmonary artery is taken in similar fashion on the right, but extrapericardially on the left. Each vascular division is done using the endoleader technique and the endoscopic stapling device. Posteriorly, the pericardium is opened at the level of the esophagus on the right and the aorta on the left. The subcarinal lymph nodes are then removed, and the bronchus is divided last using a heavy-wire stapler. The ability to visualize this bronchoscopically during the dissection aids in achieving the proper bronchus length. A short, almost flush bronchial stump reduces the possibility of stump syndrome from airway secretions and helps minimize stump breakdown.

Once the specimen has been removed, additional lymph node stations are sampled and the bronchial stump is leak tested. At this point, a chemical wash is performed, followed by intracavitary heated chemotherapy consisting of cisplatin and gemcitabine for 1 hour. If the patient has a creatinine clearance of less than 60 mL/min or crowded optic disc on preoperative assessment, the length of intracavitary chemotherapy should be reduced by half. Next, the omentum is mobilized for use as a bronchial stump buttress. Alternatively, this can be covered with a pericardial fat pad buttress. Next, the diaphragm and pericardium are reconstructed using 2- and 1-mm expanded polytetrafluoroethylene (e-PTFE) patches, respectively (Gore-Tex Dual Mesh; WL Gore, Flagstaff, AZ) (Fig. 31-2). A series of nine stitches is used to secure the patch circumferentially from the posterior paraspinous ligament around to the sixth costal cartilage anteriorly. Gore-Tex buttons or bumpers are used to keep the sutures from pulling through the chest wall (Fig. 31-3). The dynamic two-piece diaphragm patch is then sewn to the base of the pericardium from the anterior costophrenic angle posteriorly toward the esophagus and inferior vena cava (right) or aorta and crus (left) (Fig. 31-4). The impermeable nature of the patch prevents peritoneal fluid from freely crossing into the pleural space postoperatively.

The pericardial patch is fenestrated and sewn in place posteriorly first. It is then secured to the diaphragmatic patch inferiorly and the residual pericardium anteriorly and superiorly (Fig. 31-5). It should not be made too tight because this may constrict filling of the heart, causing a tamponade effect. This is more important on

FIGURE 31-2 ■ Creation of the diaphragmatic patch. Two 2-mm impermeable Gore-Tex patches (Gore-Tex Dual Mesh; WL Gore, Flagstaff, AZ) are overlapped, stapled together, and trimmed to create a dynamic patch with reduced tension along its edges. Nine holes are made along the periphery of the patch to receive interrupted 0 Gore-Tex sutures.

FIGURE 31-3 ■ Diaphragmatic reconstruction. The sutures on the patch are pulled through the chest wall with an awl and securely tied, from the paraspinous ligament posteriorly to the sixth rib anteriorly. Polytetrafluoroethylene (PTFE) buttons or bumpers are placed to prevent the sutures from pulling through the chest wall.

the right side, given the potential for the heart to turn about the axis of the cavae and herniate. In fact, the left-sided pericardium does not always have to be patched. Once the patches have been placed, an elliptical opening is made in the diaphragmatic patch, and the omentum is pulled through this aperture (Fig. 31-6). It is secured to the bronchus, primarily, with additional bites taken along the surrounding tissues to minimize direct tension. The diaphragmatic patch can be reefed up between the two pieces that make up the dynamic patch, with care not to

FIGURE 31-4 ■ Completion of patch reconstruction. The posterior or mediastinal edge of the diaphragmatic patch is sutured to the inferior cut edge of the pericardium. Care is taken to avoid constriction of the inferior vena cava (right side), slitting the patch if necessary, and to avoid intra-abdominal herniation (left side) with healthy bites along the crus and posterior chest wall.

FIGURE 31-5 ■ The pericardial patch is secured to the posterior, anterior, and superior cut edges of the pericardium. Inferiorly, it is sutured to the diaphragmatic patch itself. Depending on patient size, it may be necessary to splice in an additional patch to avoid cardiac or caval constriction. Displacement of the heart into the pneumonectomy space after closure needs to be taken into account when sizing the pericardial patch during implantation. The pericardial patch should be fenestrated before reconstruction to reduce the chance of pericardial tamponade from fluid accumulation behind the patch.

make the neodiaphragm too tight. Additional bites are taken to secure this patch with the chest wall and diaphragmatic crura posterolaterally. Thorough hemostasis is achieved with an argon beam coagulator. The thoracotomy is closed in standard fashion with care to make it watertight. A 12-Fr red rubber catheter is left in place for use in balancing the mediastinum intraoperatively. In men, 1000 mL is removed initially after a right EPP (750 mL from the left), whereas in women, 750 mL is taken from the right chest (500 mL from the left side). Additional air is removed in the postoperative setting as needed based on the chest radiograph, with the intention of removing the catheter altogether by the third day to reduce infection.

FIGURE 31-6 ■ A portion of omentum can be mobilized and carefully pulled through the patch to serve as a buttress on the bronchial stump to help prevent bronchopleural fistula.

Pleurectomy is a palliative debulking procedure that is combined with decortication for patients with mesothelioma whose pulmonary function or physiologic status contraindicates pneumonectomy. The incision and initial dissection are identical to that described for an EPP. Once the parietal pleura has been dissected free, the tumor itself is incised down to the visceral pleura for an internal pleurectomy. Bleeding can be controlled with an argon beam coagulator or hilar clamping, if needed. It is important to remove as much tumor tissue as possible, especially that extending into the fissures, for a macroscopic complete resection.²²¹ On the right side, reconstruction of the diaphragm is not always needed, because the liver is there and the lung is left in place.

Postoperative Management. Key points in successful recovery of patients in the postoperative setting include pain management, careful fluid balance, and early vigilance for, and diagnosis of, common postoperative complications, which include deep venous thrombosis, pulmonary embolism, vocal cord paralysis, chylothorax, empyema, bronchopleural fistula, and mediastinal shift.²²² Pain is controlled with a thoracic epidural and a patient-controlled analgesia (PCA) pump when needed. Proper pain control and vigorous ambulation (after an initial 48-hour period of mediastinal equilibration for pneumonectomy patients) are critical to preventing contralateral lung atelectasis. The Swan-Ganz catheter is left in place and removed on postoperative day 2 with the expectation that there will be massive fluid shifts. Patients are often vasoplegic as a result of the systemic inflammatory response of the intracavitary chemotherapy and dissection of the sympathetic trunk. Aggressive ambulation begins after the pulmonary artery catheter is removed and will progress over the ensuing days. Patients are given a nasogastric tube and nothing by mouth for the first 48 hours. Diet is then advanced as tolerated. Because aspiration can have devastating consequences in any patient with a voice change or signs of aspiration, there is a low threshold for evaluating the vocal cords in this patient population. Fluid restriction and liberal use of diuretics help achieve proper fluid balance: pulmonary

edema is a dreaded complication of pneumonectomy. Perioperative beta blockade is administered for prophylaxis of atrial fibrillation. Aggressive screening and prophylaxis for deep venous thrombosis is carried out in every patient with venous duplex Doppler exams on a weekly basis for the first several weeks after surgery.

Operative Results. Several large studies of pleurectomy for mesothelioma have been reported. A series from Memorial Sloan Kettering Cancer Center listed a mortality rate of 1.8%, complication rate of 25%, and 1-year survival of 49% in 64 patients.²²³ In Germany, Achatz and colleagues reviewed 245 partial and complete pleurectomy cases and showed a 30-day mortality of 8.5% with a median survival of 9.2 months.²²⁴ In 1991, Brancatisano and associates described a series of 45 pleurectomy patients with a mortality rate of 2.2%, morbidity rate of 16%, and median survival of 16 months.²²⁵ Allen and coworkers reported a series of 56 patients with a perioperative mortality of 5.4%, morbidity of 26.8%, and 1-year survival of 30%.²²⁶ More recently, Richards and colleagues reported a retrospective analysis of patients under a protocol for a combined regimen of cytoreduction surgery (pleurectomy or EPP) plus intraoperative intracavitary chemotherapeutic lavage with hyperthermic cisplatin.²²¹ In a subgroup of patients undergoing pleurectomy at two different dosages of hyperthermic drug delivery—low dosage (50 to 150 mg/m²) versus high dosage (175 to 250 mg/m²)—the study found that the subset of patients receiving high-dose chemotherapy demonstrated an apparent survival benefit warranting further investigation. The EPP arm of this phase I study, published in 2009, reported overall median survival of 17 months (resected 20 months; unresected 10 months). Median survivals for patients receiving the higher cisplatin dose was 26 months, and for patients receiving the lower dose, median survival was 16 months ($P = 0.35$).²⁷⁴

Extrapleural pneumonectomy carries a higher mortality rate compared with that of pleurectomy in most series. The perioperative mortality in Butchart's original series was 30%, which was comparable to that of contemporary studies in the 1970s.¹⁸² Since then, experience from high-volume centers has shown a significant reduction in mortality from EPP to rates of less than 10%. DaValle and colleagues²²⁷ published a mortality rate of 9%, and Rusch and coworkers²²⁸ reported a rate of 6%. Recently, Sugarbaker's group reported a perioperative mortality of 4% and morbidity of 66% for this procedure.^{229a}

In addition to the surgical approach, lymph node involvement has also been an important factor in overall survival after EPP or P/D. Hysi et al conducted a multicenter retrospective study in France and concluded that lymph node involvement and metastatic lymph node ratio influence survival.²²⁹ They found that node-positive resection specimens significantly reduced median survival (22.4 months for N0 versus 12.7 months for N+ patients, $P = 0.002$). The lymph node ratio was also important in that a lower metastatic lymph node ratio (<13%) was associated with a significantly improved median survival (19.9 months versus 11.7 months, $P = 0.01$). Interestingly the number of lymph nodes removed or involved was not related to survival; only the lymph node ratio was related

to survival, therefore promoting lymph node ratio as a more reliable prognostic factor.

Multimodality Therapy

Early efforts to treat MPM with single therapies failed to have a significant impact on patient survival (Box 31-5). As a result of these failures, a multimodality strategy evolved. The multidisciplinary approach for surgical candidates includes P/D or EPP, external beam radiation to the hemithorax, and systemic combined chemotherapy. Treatment plans involving two modalities, such as chemotherapy and surgery, radiation and surgery, or chemotherapy and radiation, have shown some improvement over single-modality treatment in nonrandomized studies. Chemotherapy or radiation without surgery has had very limited success.²³⁰ Surgery, either as P/D or EPP, combined with chemotherapy or radiation has been found to show some improvement in survival when compared with historical controls. Rusch and colleagues from Memorial Sloan Kettering Cancer Center reported a series of 105 patients with MPM who underwent P/D combined with intraoperative brachytherapy plus adjuvant external beam radiation.¹⁸³ Median survival was 12.5 months, with local relapse the most common treatment failure. In another study from the same institution, 28 patients with mesothelioma underwent P/D, this time in conjunction with intrapleural and adjuvant systemic chemotherapy.²³¹ Overall survival was 68% at 1 year and 40% at 2 years, with locoregional disease the most common relapse.

A seminal article in 1980 by Antman and associates advocated a multimodality approach to malignant mesothelioma after a retrospective review suggested an advantage to aggressive intervention.²³² Antman initiated a prospective multimodality protocol that included EPP followed by adjuvant chemoradiation. In 1991, Sugarbaker reported his first case series of 31 patients who

BOX 31-5 Therapeutic Options for Malignant Pleural Mesothelioma

SINGLE-MODALITY THERAPY

- Debulking surgery (pleurectomy/decortication or extrapleural pneumonectomy)
- Radiation (external beam, brachytherapy)
- Chemotherapy (single- or double-agent approach: doxorubicin, cyclophosphamide, cisplatin; gemcitabine, pemetrexed [see reference 267], and cisplatin)

MULTIMODALITY THERAPY

- Surgery and adjuvant radiation
- Surgery and adjuvant chemotherapy
- Surgery and adjuvant chemoradiotherapy

INNOVATIVE THERAPIES UNDER INVESTIGATION

- Intracavitary lavage with hyperthermic chemotherapy
- Photodynamic therapy
- Gene therapy
- Angiogenesis
- Immunogenic therapy

underwent EPP in a trimodality setting. The mortality rate was low (6%), and this study identified trends toward improved survival in the subset of patients with negative histologic margins.²³³ During this period, other centers produced case series with improved mortality rates after EPP.^{189,227}

A prospective trial by Rusch and coworkers noted a longer progression-free survival with EPP but showed no difference in survival when compared with patients who underwent less radical procedures or nonsurgical treatment.²²⁸ Allen and colleagues published a retrospective case series of patients who underwent either pleurectomy or EPP with adjuvant chemotherapy or radiation therapy.²²⁶ There was a trend toward higher median survival in those who underwent EPP, but it was not statistically significant. Sugarbaker's group described a substantial reduction in operative mortality (4.6%), and in 1993, the Brigham and Women's Hospital/Dana-Farber Cancer Institute combined cancer treatment program identified a subset of patients with epithelial histology and node-negative status that exhibited improved survival.^{234,235} The next update in the Brigham series reported a median survival of 21 months in 120 patients.¹⁸⁶ Based on the Brigham staging system, median survival was 22 months for stage I, 17 months for stage II, and 11 months for stage III disease. These data were subsequently updated in 183 patients using the revised Brigham staging system, where N2 disease was reclassified as stage III (instead of stage II) disease, beyond the pleural envelope.¹⁸⁵ This reclassification was in response to a multivariate analysis that showed that the most important predictor of poor outcome after EPP in a trimodal setting was histologic subtype (nonepithelial), positive N2 nodal disease, and positive resection margins.

During this time, the IMIG consortium led by Rusch developed another staging system (see [Box 31-3](#)).¹⁸⁴ TNM staging designates most patients as stage III, which has the effect of coalescing patients with different tumor characteristics and obscuring survival benefits associated with such prognostic markers. Nonetheless, the TNM staging system continues to be more widely used. Rusch published a prospective noncontrolled study of a cohort of mesothelioma patients treated with either EPP or pleurectomy followed by adjuvant treatment. Tumor stage had a significant impact on overall survival when considered across all stage groups: stage I had a median survival of 30 months, stage II 19 months, stage III 10 months, and stage IV 8 months. Although there was no significant difference in survival based on type of surgical resection, it should be noted that pleurectomy was performed in patients with minimal visceral pleural tumor, whereas those with more locally advanced tumors underwent EPP.¹⁸⁴ It is important to recognize such a selection bias in operative planning when interpreting results.

As there is much controversy as to the importance of type of surgical resection (P/D versus EPP), the issue is likely to remain unresolved in the absence of randomized controlled trials comparing the two approaches. A recent case series by Stewart and colleagues supports the benefit of EPP over P/D by demonstrating a longer progression-free survival and longer time to local disease progression with EPP.²³⁶ Studies of patterns of failure

after multimodality therapy have implicated locoregional recurrence as the most common site of treatment failure. Baldini and colleagues revealed that 25 of 46 patients (54%) developed documented recurrences, with a median time to recurrence of 19 months. The ipsilateral hemithorax was the most common site of recurrence (35%), followed by the abdomen (26%), contralateral hemithorax (17%), and distant disease (8%).²³⁷ This study clearly indicates the locally aggressive nature of malignant mesothelioma and suggests that more effective methods to prevent locoregional recurrence are needed after macroscopic complete resection of this tumor.

Local Recurrence. The ipsilateral hemithorax is the most common site of recurrence after malignant mesothelioma. Burt and colleagues recently illustrated the beneficial effects of local chest wall resection for recurrent mesothelioma.²³⁸ They found that, out of 1142 patients from 1988 to 2011 who underwent EPP or radical pleurectomy for mesothelioma, 47 (4.1%) had chest wall recurrence amenable to resection. The predominant area of recurrence was peri-incisional (49% of cases), followed by the costophrenic angle (38%). There was no 30-day mortality following chest wall resection, and median length of stay in the hospital was 3 days. Overall median survival duration after resection for recurrence was associated positively with time to recurrence. Patients with epithelial pathology had median survival of 8.9, 17.2, and 35.8 months with a time to recurrence of less than 12 months, 12 to 24 months, and more than 24 months, respectively. The authors concluded that chest wall resection is a safe and effective method of managing local recurrence and that time to recurrence appears to predict survival, with decreased time to recurrence being associated with worsening overall survival.

Innovative Adjunctive Therapies

Intraoperative Heated Chemotherapy. Intracavitary chemotherapy has been studied in patients with abdominal malignancies as a means of improving locoregional control.^{239,240} With intracavitary administration, the chemotherapy agent enters the tumor cells directly by diffusion, thereby minimizing the toxicity associated with systemic delivery. The depth of penetration for chemotherapy agents is only several centimeters deep from surface application²⁴¹; however, this may be sufficient for locoregional control if microscopic control is needed after gross tumor removal. It is important to achieve a macroscopic complete resection before the administration of intracavitary chemotherapy to ensure complete exposure of the chemotherapeutic agent to all surfaces that may harbor cancer cells.²²¹ The optimal timing for chemotherapy lavage is in the operating room immediately after tumor resection and before the development of adhesions. This allows maximal drug exposure to occur before tumor cells become entrapped in fibrinous exudates and loculated adhesion pockets. In addition, the best time for drug delivery is immediately after resection, when the volume of residual tumor cells is small enough to be penetrated by the chemotherapy drug.

Systemic absorption of intrapleural chemotherapy will occur, with peak plasma levels occurring within 1 hour of intrapleural administration of cisplatin; however, there is a local advantage with respect to pleural in comparison to plasma levels using this drug delivery system.²⁴² Intraoperative caution is needed with respect to crystalloid infusion to prevent postpneumectomy pulmonary edema, and there is also significant concern about renal toxicity because of potential systemic absorption of

cisplatin. Adjunctive methods to mitigate the potential for renal toxicity include the intraoperative administration of thiosulfate and amifostine as cytoprotective agents in combination with intravenous hydration postoperatively.

Hyperthermia has been shown to increase cell permeability, alter cellular metabolism, and improve membrane transport of drugs.²⁴³ A synergistic effect of hyperthermia and cisplatin has been demonstrated (Table 31-2).^{244,245} Initial studies with this approach after EPP suggested

TABLE 31-2 Hyperthermic Intracavitary Chemotherapy Studies

Study	Patients (N)	Surgery (Number of Patients)	Intracavitary Chemotherapy	Overall Median Survival (mo)	Cytoprotection	Renal Toxicity (Number of Patients)

that median survival could be increased to 18 months²⁴⁶ and, in selected patients, long-term control could be achieved.²⁴⁷ Tilleman and colleagues have recently reported a series of 121 patients treated with heated intraoperative chemotherapy after EPP.²⁷⁶ In this series, in the group of patients who completed the protocol, there was a mortality of 1.1% and a postoperative morbidity of 48.9%, with significant renal toxicity of 9.8%. The overall median survival of the treatment cohort was 13.1 months, with a cancer-specific survival of 16.9 months. However, in patients with epithelial histology and early-stage disease (Brigham and Women's Hospital stage I or II), there was an improved cancer-specific median survival of 21.4 months and 22 months, respectively.²⁴⁸

Because of the potential for local recurrence in the hemithorax and for regional relapse in the abdomen, the practice of bicavitary intraoperative heated chemotherapy is now used in conjunction with EPP or P/D as part of a multimodality treatment approach in patients with mesothelioma.

Antiangiogenic Therapy. Angiogenesis plays a central role in tumor growth and therefore lends itself as a target in the treatment of cancer patients. Three antiangiogenesis inhibitors currently under trial are thalidomide, SU5416, and bevacizumab. Thalidomide is one of the few antiangiogenic agents available for oral administration. It has shown promise in prolonging disease stabilization with a relatively mild toxicity profile.²⁴⁹ Studies involving the other two drugs involve VEGF, and endpoints include time to progression of disease and tumor response rate. SU5416 is an inhibitor of the VEGF-1 receptor Flk-1 and is being studied by the National Cancer Institute, and bevacizumab is a recombinant anti-VEGF monoclonal antibody under investigation at M. D. Anderson Cancer Center, the University of Chicago, and the University of Pennsylvania.²⁵⁰

Photodynamic Therapy. Photodynamic therapy (PDT) is a two-step process that involves first the administration of a photosensitizing agent, such as Photofrin or Foscan. Tumor cells preferentially take up these compounds. The second step involves exposing the affected tumor tissue to light at a certain wavelength. This light catalyzes a cellular reaction in which free radicals are produced and ischemic necrosis occurs. These events lead to damage from direct cytotoxic effects on cellular membranes and from vascular occlusion. Because the depth of tissue penetration of the light is limited, PDT is well suited for use as an intraoperative adjunct after surgical debulking.

Applications of this therapy in mesothelioma patients have been ongoing at a few centers.²⁵¹⁻²⁵⁴ Takita and his group studied Photofrin in 40 patients from 1991 to 1996.²⁵³ Patients underwent pleurectomy or extrapleural pneumonectomy for removal of all gross disease or had their tumors debulked to a depth of less than 0.5 cm; intraoperative PDT followed. Median survival for patients in stages I and II was 36 months and was 10 months for patients in stage III and IV. Because of its better profile in terms of increased oxygen singlet

production and decreased duration of skin photosensitivity, the photosensitizer Foscan was studied in 26 patients undergoing P/D or EPP in a phase I trial from 1997 to 2001.²⁵¹ Median progression-free survival and overall survival were each 12.4 months. These preliminary results will probably lead to a phase II trial.

Immunotherapy. Several studies suggest that mesothelioma cells are susceptible to destruction by immunologic means.²⁵⁵ Boutin described the activity of intrapleural recombinant interferon- γ (IFN- γ) against malignant mesothelioma in 1991.²⁵⁶ His group has also made use of an implantable access system for prolonged administration of the immunotherapy agents directly into the affected hemithorax, reducing the toxicity and allowing treatment on an outpatient basis.²⁵⁷ A prospective multicenter study of 89 patients with early-stage disease showed an overall response rate of 20%, and the treatment was well tolerated.²⁵⁸ The exact mechanism of action is not clear, but it may relate to an IFN- γ -mediated inhibitory effect on interleukin-6 (IL-6) production, which may abrogate the systemic manifestations associated with mesothelioma cells.²⁵⁹

Other work has been done using the cytokine interleukin-2 (IL-2), which is known to stimulate proliferation of T cells, natural killer cells, and lymphokine activated killer cells. Repeated intrapleural instillation of IL-2 was given twice weekly for 4 weeks during a phase II trial in 31 patients, 22 of whom were in stage I.²⁶⁰ Pleural fluid collections were effectively treated in 90% of patients, and median overall survival was 15 months. In another study, treatment with IL-2 yielded an overall response rate of 47% in a phase I trial and 55% in phase II testing.²⁶¹ Monti and coworkers demonstrated the *in situ* activation of CD8⁺ cells and macrophages after the administration of IFN- γ .²⁶² Despite the theoretical considerations, a phase II trial using an infusion of activated macrophages and IFN- γ did not show an improvement in antitumoral activity.²⁶³

Gene Therapy. Gene transfer techniques can be used to alter cells to enhance immunogenicity. This can be done in several ways, including by transfection and expression of genes for various cytokines and costimulatory molecules.²⁶⁴ In a murine model of mesothelioma, flank tumors were treated with adenovirus-encoding interferon- β (IFN- β).²⁶⁵ Tumors treated before debulking increased long-term tumor-free survival and resulted in twofold to sixfold smaller foci of implanted tumor cells at 2 weeks postoperatively. It was postulated that elimination of residual tumor cells occurred because of an amplification of the cytotoxic T-lymphocyte antitumor response mediated by adenovirus-encoding IFN- β .

Recently, a small study of 21 patients with mesothelioma used high-dose therapy with a vector that encoded the herpes simplex virus thymidine kinase.²⁶⁶ A spectrum of clinical responses was observed, including in two patients followed for 6 years after gene transfer therapy. It is thought that in the future, augmenting the immune effects of gene transfers may lead to increased numbers of therapeutic responses.

SUMMARY

The muscular diaphragm acts as a boundary between the positive-pressure abdominal cavity and the negative-pressure thoracic cavity. Perhaps because it is a boundary structure, or perhaps because the horizontal diaphragm is poorly visualized on a plain chest radiograph and computed tomography (CT) scan, discussion of the surgical approach to the diaphragm is neglected in many surgical textbooks.

In our opinion, there is some misinformation about the surgical treatment of the diaphragm in the current literature. This misinformation seems to reflect a lack of understanding of the basic anatomy and physiology of the diaphragm. Although diaphragmatic disease is infrequent, exposure to the diaphragm is commonplace because it is visualized during every thoracic surgical procedure and most intra-abdominal operations. Therefore, the basic principles advocated by this chapter can be verified or denied in the operating room.

Two fundamental principles can be applied to all surgical approaches to the diaphragm: (1) the muscles contract in a radial manner like the spokes of a wheel; and (2) the balance of positive pressure pushing up from the abdomen and negative pressure within the thorax created by the elastic recoil of the lung during quiet expiration displaces

the central tendon into the chest, whereas contraction of the diaphragmatic muscle pulls the tendon back toward the costal margin and elevates the lower ribs, enlarging the volume of the thorax. We hope to apply these two fundamental principles in an understanding of the physiology and pathophysiology of the diaphragm. Furthermore, we believe that these two principles will allow physicians to use new technologies and to develop better operations to treat diaphragmatic disease.

EMBRYOLOGY

In utero, the diaphragm forms from the septum transversum and pleuroperitoneal folds.¹ The septum transversum is an unpaired ventral membrane that separates the pericardium from the remainder of the thorax and creates the central trileaflet of the diaphragmatic tendon (Fig. 32-1).² One of the trileaflet tendons lies within the right hemithorax, one within the left hemithorax, and the third beneath the pericardium. The dorsolateral portions of the diaphragm start with the formation of pleuroperitoneal folds. The mesothelium of the pleura binds to the mesothelium of the peritoneum in a membrane only two

FIGURE 32-1 ■ **A** and **B**, Transverse schematic of developing embryo during weeks 5 to 7. Bilateral pleuroperitoneal folds extend anteriorly to reach the posterior edge of the septum transversum, thus forming the posterior portions of the diaphragm. The septum transversum develops into most of the central tendon. (From Larsen W: *Human embryology*, ed 2, New York, 1997, Churchill Livingstone.)

cell layers deep. Myotomes from C3, C4, and C5 then migrate from the lateral border toward the center of each hemithorax within the interspace between these two mesothelial layers in the seventh week of life. The outer rim of muscle of the diaphragm is from myotomes that carry nerve innervation from T7 through T12.² The intestines return to the abdomen from the yolk sac in the 10th week of life and will be displaced into the chest if the diaphragm has not successfully formed (a congenital diaphragmatic hernia).

STRUCTURE AND FUNCTION

This simplified embryologic description provides several fundamental concepts of diaphragm function and pathology. Muscle contraction is in a radial manner along the lines of migration of the myotomes. Thus, fiber shortening is along the lines of a wheel spoke, between the central tendon and the circumferential rib cage. Furthermore, any congenital loss of muscle or tendon may present as a hernia within the diaphragm.

In the adult, each hemidiaphragm resembles the surface of an upside-down fairway wooden golf club. The fan-shaped tendon is like the flat metal sole plate, and the circumferential muscle curves away into the sulcus like the curved wooden club head. The muscle fascicles of the crus coalesce and attach to the lumbar spine, just as the wooden club curves down to attach to the metal shaft.

The diaphragm has three natural openings (Fig. 32-2). The aortic opening is the most posterior of the three and is formed from fibers composing the right and left diaphragmatic crura.³ This tunnel is actually behind the diaphragm, not within it, and contains the aorta, azygos vein, and thoracic duct. The esophageal hiatus is slightly more ventral from the aortic hiatus and consists of fibers passing between the aorta and the esophagus toward the right crus and fibers converging on the pericardial tendon. The opening of the inferior vena cava lies within the confluence of the tendons of the right hemithorax and the tendon beneath the pericardium.

The fan-shaped muscle of the diaphragm arises from the internal circumference of the thorax, with attachments to the sternum, the lower six or seven ribs, and the vertebral bodies of the lumbar vertebrae. Posteriorly, the muscle fibers originate from the aponeurotic arch of the ligamentum arcuatum externum, which overrides the psoas and quadratus lumborum muscle. Laterally, the fibers of the diaphragm interdigitate with slips from the transversalis muscle of the abdomen as they originate from the ribs.³ The right crus is larger and longer than the left and arises from the bodies of the upper three or four lumbar vertebrae. The left crus arises from the upper two lumbar vertebral bodies.

During inspiration, the first rib is elevated and fixed by the scalene muscles of the neck. The external intercostal muscles raise, in turn, each of the lower ribs. Raising these ribs, like a bucket handle that is attached to the sternum and vertebral column, enlarges the thorax and creates the negative pressure that ventilates the lung.³

The diaphragm is the major muscle of inspiration.⁴ In the resting state, the central tendon is displaced cephalad into the thorax by the positive intra-abdominal pressure. During contraction, the radial muscle fibers pull the tendon down toward the abdominal cavity like a drum-head. This further augments the negative intrathoracic pressure and further increases the positive pressure in the abdomen. The diaphragmatic crura contribute to the magnitude of displacement of the central tendon. In fact, if there were only circumferential attachments to the rib cage, the diaphragm would be limited in its ability to displace the lower ribs and to enlarge the thoracic cavity. The thicker fascicles of the crura, which lie at a 45- to 90-degree angle to the plane of the fan, pull on the anchoring lumbar spine like a lever and thus fix the central tendon in place. In descending, the fan of the diaphragm displaces the intra-abdominal viscera, which do not yield completely because they are bolstered by the anterior abdominal wall. The central tendon becomes a fixed point from which the radial muscles of the fan contract and are thus able to elevate the lower ribs. Even though the points of muscle attachment to the

FIGURE 32-2 ■ Superior (A) and inferior (B) views of the diaphragm, including phrenic nerve anatomy. The intradiaphragmatic course of the phrenic nerves is often difficult to visualize at the time of surgery. Familiarity with the nerve's path as it traverses the muscle is helpful in deciding where to make diaphragmatic incisions.

lumbar spine are more caudal than the attachments to the rib cage, the domed tendon acts as a fulcrum cephalad to the attachments to the rib cage. In fact, contraction of the diaphragm can raise the lower ribs only if the intra-abdominal viscera are in situ and not if the organs have been removed.³ Injuries to the crura have a more disproportionate effect on the respiratory function of the ipsilateral diaphragm than a similar injury to the peripheral muscle.

A forced inspiration descends the central tendon one or two rib interspaces. Under normal respiration, each hemidiaphragm provides between 15% and 25% of respiratory muscle function, with each side of the combined intercostals providing the remaining percentage.^{5,6} Under strained respiration, however, the diaphragm can increase its workload to provide up to 80% of the work of breathing.

PLEURAL AND PERITONEAL ATTACHMENTS

The pleura adheres tightly to the top surface of the diaphragmatic central tendon and most of the musculature. It is impossible to separate the pleura from the central tendon of each hemidiaphragm. As the pleura curves off the chest wall and folds back on itself on the surface of the diaphragm, there is a circumferential diaphragmatic recess of approximately 1 cm that does not contain pleura.⁷ This recess of uncovered diaphragm is used to good advantage during an extrapleural dissection when the surgeon wraps his or her fingers into this recess and pulls downward, thus exposing the diaphragmatic musculature for division (Fig. 32-3).

FIGURE 32-3 ■ The parietal pleura folds off the rib cage and onto the diaphragm but does not extend into the deep recess of the diaphragmatic sulcus. A bare area of diaphragmatic muscle can be exposed with traction on the parietal pleura.

The peritoneum is less adherent to the undersurface of the diaphragm and can be bluntly mobilized off the diaphragm during extraperitoneal approaches to the abdominal aorta. The plane of dissection lies between the inferior phrenic artery and vein on the muscle side and the peritoneal membrane. The peritoneum separates from the central tendon of the right diaphragm to form the falciform ligament and produces an area directly under the central tendon that does not have peritoneal covering. This is known as the bare area.

ARTERIAL AND VENOUS ANATOMY

The superior phrenic arteries are located on the thoracic surface of the diaphragm. They are small branches from the lower thoracic aorta and traverse the posterior diaphragm over the top portion of each crus close to the mediastinum.³ They terminate in small anastomoses with the musculophrenic and pericardiophrenic arteries, which are both branches from the internal mammary artery. These two arteries also supply blood to the phrenic nerve and the pericardial fat pad.⁸

The inferior phrenic arteries lie on the undersurface of the crus and the dome of the diaphragm (Fig. 32-4). They are small paired vessels with frequent anatomic variations. They can originate separately or as a common trunk from the aorta above the celiac artery or from the celiac artery itself. Alternatively, a common trunk arising from either the aorta or the celiac artery gives rise to these two arteries. On occasion, one vessel originates from the aorta and the other emerges from one of the renal arteries. Diverging near the crura, the inferior phrenic arteries then course obliquely superior and lateral

FIGURE 32-4 ■ Arterial anatomy of the inferior diaphragmatic surface.

along the inferior surface of the diaphragm. The left inferior phrenic artery passes posterior to the esophagus and then runs anteriorly along the lateral side of the esophageal hiatus. The right inferior phrenic artery passes behind the inferior vena cava.³

Close to the posterior aspect of the central tendon, both the left and the right inferior phrenic arteries divide into a medial and a lateral branch. The medial branch extends anteriorly, close to the mediastinum. Branches of this vessel traverse the muscular portion of the diaphragm to anastomose with the musculophrenic and pericardiophrenic arteries. The lateral branch of the inferior phrenic artery courses laterally and forms anastomoses with the lower intercostal arteries. The left inferior phrenic artery provides a minor contribution to the blood supply of the lower esophagus. Both right and left inferior phrenic arteries have branches to the ipsilateral suprarenal gland; these branches are called the right and left superior suprarenal arteries.³

In general, the venous anatomy in this region parallels that of the arteries. The superior phrenic veins are small and drain anteriorly to the internal mammary vein. The much larger inferior phrenic veins parallel the course of the inferior phrenic arteries. The right vein empties directly into the inferior vena cava. The left vein usually has two branches, one of which drains into the left renal or suprarenal vein, the other of which passes anterior to the esophageal hiatus and empties into the inferior vena cava.³

LYMPHATICS

The lymphatics of the diaphragm drain toward the internal mammary chain anteriorly and the thoracic duct posteriorly. Smaller lateral lymphatic branches follow the course of the intercostal vessels along the lateral and posterior margins of the chest wall.³ Although these vessels are rarely seen in the nonpathologic state, engorged vessels are frequently seen on both upper and lower surfaces of the diaphragm in patients who have congenital heart disease with elevated central venous pressures and in primary pathologic conditions of the lymphatics, such as cavernous lymphangioma.

DIAPHRAGMATIC INNERVATION

The phrenic nerve originates from the C3, C4, and C5 nerve roots and then enters the chest anterior to the subclavian artery. On the left side, the nerve lies medial to the internal mammary artery 64% of the time; on the right side, it lies medial to the internal mammary artery only 46% of the time.⁹ Thus, the left nerve is more susceptible to injury during mobilization of the left internal mammary artery through a median sternotomy incision.

Most diaphragmatic muscle originates from cervical myotomes innervated by fibers from the spinal nerve roots at cervical levels C3, C4, and C5. These fibers join and form the phrenic nerve, which elongates as the septum transversum migrates caudally. There is, however,

an outer rim of diaphragmatic muscle that originates from migrating mesenchymal cells of the nearby body wall innervated by spinal nerves from thoracic levels T7 to T12. In addition, a contribution from mesenchyme associated with the foregut at levels L1 to L3 coalesces to form the right and left crura.^{2,3}

Despite the contributions from the thoracic and spinal nerve roots, most of the diaphragm is innervated by the phrenic nerve. Although the origin of the phrenic nerve and its proximal course through the mediastinum are well known, the distal extent of the nerve as it branches into the diaphragm proper is not as well described. In 1956, Merendino and colleagues¹⁰ published the most descriptive and often-cited reference regarding this intradiaphragmatic portion of the phrenic nerve. Their anatomic findings and frequently adapted schematized drawings are based on electrical stimulation studies and gross dissection in dogs as well as on intraoperative dissection of approximately 40 human diaphragms.

The phrenic nerve usually divides at the level of the diaphragm or just above it. The right phrenic nerve enters the diaphragm just lateral to the inferior vena cava within the central tendon. The left phrenic nerve enters lateral to the left border of the heart just anterior to the central tendon within the muscle itself. The intradiaphragmatic course of the phrenic nerve can be predicted, even when it is not directly seen, by knowing the distribution of the four main motor divisions. The phrenic nerve first splits into an anterior and a posterior trunk (see Fig. 32-2B). The anterior trunk subsequently divides into a sternal and an anterolateral branch near the anteromedial border of the central tendon. The posterior trunk likewise divides into a crural and a posterolateral branch along the posteromedial border of the central tendon. The sternal and crural branches are short and continue to run in an anteromedial and posteromedial direction, respectively. The anterolateral and posterolateral branches are much longer and run close to the muscular fiber insertions into the central tendon. These two branches innervate most of the diaphragm. Their anatomic relation to one another is often described as a pair of handcuffs or manacles. These branches are often within the muscle layers and are not readily visible.

DIAPHRAGMATIC INCISIONS

Diaphragmatic incisions can be made in various locations. Certain areas of the diaphragm can be incised safely without causing significant damage or loss of function. Other regions are likely to result in bleeding, structural weakness, or diaphragmatic hemiparesis if they are incised or cauterized inappropriately.

Diaphragmatic incisions can be divided into three groups: circumferential, central tendon, and radial. Circumferential incisions in the periphery result in little loss of function. These circumferential incisions, however, must be at least 5 cm lateral to the edge of the central tendon to avoid the posterolateral and anterolateral branches of the phrenic nerve. These incisions can be difficult to realign correctly after a long operation. Placement of surgical clips on each side of the muscular

FIGURE 32-5 ■ Curvilinear diaphragmatic incision between strategically placed surgical clips. Diaphragmatic incisions disrupt the radial tension and distort the muscular anatomy. Placement of surgical clips before incision facilitates closure with proper realignment of the diaphragmatic musculature.

incision can greatly facilitate the correct spatial orientation on closing (Fig. 32-5).

Incisions in the central tendon, as far centrally as within 2 cm of the entrance of the phrenic nerve, do not interrupt any major branch of the nerve itself. This type of incision can provide excellent visualization of the abdomen from the thorax, and vice versa. These incisions are easy to open and to close.

A transverse radial incision made from the midaxillary line centrally is relatively safe because it courses between the distal aspects of the anterolateral and posterolateral branches of the phrenic nerve (i.e., through the opening of the handcuffs). Radial incisions from the costal margin extending all the way to the esophageal hiatus, however, may result in segmental diaphragmatic paralysis if the incision transects the crural or posterolateral branches of the phrenic nerve.

TRAUMATIC DIAPHRAGMATIC INJURY

Both blunt and penetrating trauma can injure the diaphragm. Penetrating injuries to the lower thorax and upper abdomen place the diaphragm at risk of injury. The nipples, marking the most cephalad displacement of the central tendon, and the base of the 12th rib, marking the most caudal attachment of the muscle, are important landmarks that help the surgeon identify a potential diaphragmatic injury from penetrating trauma. Any missile traversing this area or knife wound within this zone may create a diaphragmatic laceration.

Blunt trauma that dramatically increases the intra-abdominal pressure may cause a central tendon rupture of the diaphragm. A common mechanism for rupture is seen in patients involved in high-speed motor collisions

who are wearing seat belts. Imminent awareness of an approaching accident can cause inspiration with tensing of abdominal muscles and contraction of the diaphragm. This increases intra-abdominal pressure and, in combination with additional force from the seat belt at impact, can result in rupture of the diaphragm at the dome or central attachments. Diaphragmatic rupture occurs in 0.8% to 1.6% of patients arriving at the emergency department with blunt trauma.¹¹ Because the liver protects the right hemidiaphragm from this mechanism of injury, most diaphragmatic ruptures from blunt trauma are recognized on the left side.

An abnormal diaphragm contour on plain chest radiograph or CT scan after a traumatic injury should raise the possibility of diaphragmatic injury. These findings may be easier to appreciate if a radiopaque nasogastric tube is in place at the time of imaging. Nonetheless, radiographic findings may still be as subtle as blurring of the costophrenic angle. Because of this subtlety, delayed diagnoses are not uncommon. Review of the literature suggests that the diagnosis is missed in as many as 66% in some series.¹² One reason for this may be that traditional CT imaging has yielded poor detection of diaphragmatic injury; however, reports of new helical CT scanners show increasing sensitivity as high as 84%.¹³ If clinical suspicion is high, minimally invasive techniques with laparoscopy or thoracoscopy may be used based on their improved detection of occult diaphragmatic laceration, especially in penetrating left thoracoabdominal injuries.

Diaphragmatic injuries that are diagnosed promptly should be explored from the abdomen with either laparotomy or laparoscopy because of the frequent association of other abdominal organ injury (liver, spleen, stomach, kidney). During insufflation, the surgeon must be prepared to place an emergent chest tube in the event that a tension pneumothorax arises from communication through the diaphragmatic hole. In those cases with a significant delay in diagnosis, injuries generally should be explored from the thorax, with either thoracotomy or thoracoscopy, because the herniated abdominal structure is frequently adherent to the ipsilateral lung.

Diaphragmatic injuries need to be repaired when they are recognized. Repair corrects or prevents complications such as respiratory compromise or herniation of abdominal viscera with the associated risk of incarceration and strangulation. If no other indication for surgical exploration is present and the diagnosis of diaphragmatic rupture remains in question, exploratory thoracoscopy, a simple and effective diagnostic procedure, should be considered. Small tears can be sutured with thoracoscopic techniques after reduction of abdominal contents displaced across the defect. Thoracoscopic exploration and repair require general anesthesia with single-lung ventilation. Timing therefore depends on underlying pulmonary and neurologic function.

Lateral avulsions of the diaphragm may require reattachment to a rib at a higher level. Diaphragmatic lacerations can be closed with nonabsorbable heavy suture, with care taken to prevent injury to the main phrenic nerve branches. If the defect is large and cannot be repaired primarily, a prosthetic mesh is a good option. In

the presence of heavy contamination during damage control surgery, use of an absorbable or biological substitute is preferable to prevent continued retraction of the defect and pleural contamination. At reoperation, if there is no remaining soilage, the mesh can be exchanged for a permanent prosthetic.

DIAPHRAGMATIC ELEVATION

The two most common causes of diaphragmatic elevation are congenital eventration of the diaphragm and phrenic nerve palsy (Fig. 32-6).

Congenital eventration of the diaphragm is a spectrum of disorders that share the underlying cause of impaired fetal myotome migration.¹⁴ Mild cases may lack only the central tendon, whereas severe cases may lack the central tendon as well as the entire muscular diaphragm. The area of congenitally missing muscle tissue is usually closed with a fused single membrane of pleura and peritoneum. This membrane is generally displaced within the ipsilateral hemithorax because of the absence of muscle.

Phrenic nerve paralysis in the child can be caused by a viral palsy, an iatrogenic injury (typically after pediatric thoracic surgery), or a traction injury to the phrenic nerve at the base of the neck after a forceps delivery. In addition, there can be congenital absence of the phrenic nerve.

Diaphragmatic elevation is poorly tolerated in neonates. The flaccid diaphragm compresses the lower lobe of the ipsilateral lung. In addition, if there is a large displacement of abdominal components into the negative-pressure thorax, this bulk mechanically shifts the mediastinum with compression of the contralateral lung. Thus, there is atelectasis of the ipsilateral lower lobe, compression of the left atrium and impediment to pulmonary venous blood flow, and contralateral lung compression with additional atelectasis.¹⁵ The end result may be complete pulmonary failure requiring intubation. Mechanical ventilation reinflates the atelectatic lungs and balances the mobile mediastinum. The ipsilateral diaphragm is shifted into the abdomen.

Surgical intervention is almost mandatory in symptomatic infants with eventration, but in the adult

population, the indications for surgery are less clear. In children, plication is readily successful in achieving weaning from ventilation. In adults, however, this is not the case. In addition, regarding nonventilated patients, the condition is better tolerated in adults, and in general, only patients with progressive symptoms should be offered surgery. Causes of eventration in adults are usually related to phrenic nerve involvement through spinal cord disease, cervical trauma, infiltration of the nerve by tumors or lymph nodes, and iatrogenic injury. In certain conditions, conservative management will eventually lead to recovery of function; however, in the remaining patients, plication remains a low-risk procedure that continues to be underused. A study of patients who underwent unilateral plication by video-assisted thoracoscopic surgery (VATS) documented substantial increases in spirometry readings at 6 months after the procedure.¹⁶ The mechanism for improvement in these patients is because of increased tension of the diaphragmatic barrier between the thorax and abdomen. This allows patients to generate a more negative intrapleural pressure than is possible with a floppy, paralytic diaphragm.

Various techniques have been described in the literature for plication of the diaphragm. Severe forms of congenital eventration of the diaphragm with only a pleuroperitoneal membrane will require patching.¹⁴ A rim of rudimentary diaphragmatic tissue can generally be found around the lateral contour of the chest with enough substance to hold sutures to anchor the patch. Along the medial side, the patch can be stitched to the pericardium and the anterior thoracic spinal ligaments.

The easiest technique of plication is to place imbricating stitches within the central tendon of the diaphragm.^{17,18} If the sutures extend far enough from the edge of the diaphragmatic tendon, they can produce substantial caudal displacement of the tendon toward the abdominal cavity and allow expansion of the ipsilateral lower lobe as well as balancing of the mediastinum (Fig. 32-7).¹⁹ The central tendon can be repaired with thoracoscopic, laparoscopic, or hybrid techniques. With improved video-scopic equipment and experience, the trend toward less invasive procedures will continue and may encourage more physicians to refer their patients for surgery. Mouroux and colleagues²⁰ described a series of 12 patients

FIGURE 32-6 ■ **A**, CT scan of left diaphragmatic elevation. Note the lung tissue at the anterior and posterior thorax. **B**, CT scan of Morgagni hernia. Note the lack of lung tissue at the extreme hemithorax.

FIGURE 32-7 ■ **A** and **B**, Diaphragmatic plication by pleating of the central tendon. Sutures extend beyond the junction of the central tendon with the muscle and should not directly strike the branches of the phrenic nerve. Unfortunately, the phrenic branches lie within the muscle and frequently cannot be visualized.

who underwent thoroscopically assisted plication with a utility 5-cm incision. A Duval grasper is used to invaginate the apex of the eventration caudad, creating a fold that is closed in two layers. A VATS reproduction of the traditional pleating or “accordion” repair was performed by Freeman and colleagues¹⁶ in 22 patients with use of an Endo Stitch device (Ethicon Endo-Surgery, Cincinnati, OH) to create six to eight parallel U stitches for patients with unilateral diaphragm paralysis. Improvement in pulmonary function and quality of life was seen along with a shortened hospital stay compared with patients who underwent thoracotomy. A total thoroscopic technique with three ports has been described by Kim and associates²¹ and uses the additional adjuncts of carbon dioxide insufflation and steep reverse Trendelenburg position to push the diaphragm down and to increase the effective working space. Laparoscopic plication with four working trocars has been performed by Huttel and colleagues.²² Retention sutures are placed on the dome of the diaphragm and then used for traction. This allows creation of an intra-abdominal fold for plication with 12 to 15 U-type sutures. Finally, to counter the difficulty in placing adequate sutures through minimal access techniques, Moon and coworkers²³ reported grasping and rolling of the redundant diaphragm followed by placement of noncutting linear endoscopic staplers underneath for creation of folds that are left in situ.

Because of the rarity of diaphragmatic surgery for eventration and the multitude of presentations, a true randomized study to compare these methods is difficult, and at present, most surgeons will continue to practice the procedure with which they are most familiar. The drawback of the previous techniques, however, is that most of the pleats will fold the noncompliant central

FIGURE 32-8 ■ Original description of a radial plication technique by David State in 1949. A generous subcostal incision was used, and the muscle was sewn circumferentially to the lateral chest wall and crus to make the tendon taut.

tendon. The compliant muscular remnant can be expected to stretch with time. It has been our experience that the central tendon pleating technique is associated with re-elevation of the diaphragm to the level of the hilum within several years. Long-term follow-up of this technique has included reports of recurrent diaphragmatic elevation requiring additional intervention in as many as 19% of treated patients.²⁴ Furthermore, the phrenic vessels and branches of the nerve travel near the insertion of the muscle into the edge of the tendon and cannot be visualized from the thoracic surface of the diaphragm. Yet, to adequately displace the central tendon, these stitches need to extend into the muscle area, and this places the branches of the nerve at risk of injury. For these reasons, our preference is the radial plication method, which we believe more closely approximates the natural physiology of the diaphragm.

David State first described a subcostal radial plication technique for congenital eventration of the diaphragm in 1949.²⁵ The original description of this technique included a generous incision across the right upper quadrant of the abdomen and placement of radial sutures along the muscular portion of the diaphragm, pulling it toward the lateral chest wall (Fig. 32-8). A transthoracic radial plication has also been described.^{19,26}

John Foker at the University of Minnesota has used a transthoracic radial plication technique since 1976 to treat 35 children with elevation of the diaphragm as described by Jaklitsch and colleagues.²⁷ The repairs were performed with interrupted horizontal mattress pledgeted sutures, imbricating the muscular portion of the diaphragm in a radial manner toward the chest wall through a posterolateral thoracotomy (Fig. 32-9). The plication sutures extended in an unbroken band from the xiphoid area to the vertebral body. No sutures were placed along the mediastinal pleura. The goal was to

FIGURE 32-9 ■ A-D, Radial plication of the diaphragm with interrupted double-pledgeted sutures extending from the xiphoid to the vertebral spine. Each suture pleats the flaccid muscle to the lateral chest wall.

FIGURE 32-10 ■ Thoracoscopic port placement for radial plication in an adult. ICS, Intercostal space. (From Mouroux J, Padovani B, Poirier NC, et al: Technique for the repair of diaphragmatic eventration. *Ann Thorac Surg* 62:905–907, 1996.)

produce a taut diaphragm that appeared as a straight-angled line from mediastinum to chest wall on the anteroposterior view of the chest radiograph. We believe that this produces a plication that mimics the contraction of the fan-shaped muscle while minimizing injury to the branches of the nerve or vessels.

In this series, 31 of the 36 operations (86%) led to extubation within 3 days, even though 15 patients had been ventilator dependent before plication.²⁷ There were no deaths within 30 days, and no morbidity was directly attributed to plication. Only one patient (3%) suffered a recurrence requiring repeated plication. Twenty-six of these patients survived long term (median, 12 years at time of analysis), and 18 of these patients were reevaluated with diaphragmatic ultrasound examination in 1996. Some degree of function had returned to 14 (78%) of the diaphragms.

We have extended this technique, with some success, to a thoracoscopic approach in adults with elevated hemidiaphragms (Fig. 32-10). Currently, we use a three-port technique, with an anterior and posterior port at the sixth and eighth intercostal space, respectively. The third port is subcostal and is used to pass an O-ring clamp through the abdominal cavity to grasp the undersurface of the

central tendon of the diaphragm. This allows the caudal displacement of the muscle to see the muscular imbrications for plication. The posterior thoracic port is then used to plicate the anterior and lateral borders of the muscle; the anterior thoracic port is used to plicate the lateral and posterior borders.

DIAPHRAGMATIC HERNIAS

Several types of hernias involve the diaphragm, including hernias of the foramen of Morgagni, hernias of the foramen of Bochdalek, and central tendon and paraesophageal hernias.

The foramen of Morgagni is a potential space that lies in the parasternal area where the internal mammary vessels pass from the thoracic cavity into the upper abdominal cavity. Slips of diaphragmatic muscle insert medially onto the back of the xiphisternum and laterally to the costal margin (see Fig. 32-2B). This produces a small triangular gap of muscle tissue around the mammary vessels.

In the presence of increased intra-abdominal pressure, omentum, small intestine, or colon can pass through this defect into the anterior mediastinum. Dull pain along the right subcostal area is the most common presenting symptom. Other hernias are found incidentally on radiographic imaging for unrelated reasons. Foramen of Morgagni hernias are more common in women, in obese individuals, and on the right side because the left side is partially occluded by the pericardial sac. These hernias appear as a density in the parasternal area. CT scans of the chest are helpful in distinguishing these hernias from the pericardial fat pad or a pericardial cyst (see Fig. 32-6B).²⁸

Foramen of Morgagni hernias are frequently repaired from an abdominal approach. Both laparoscopic and thoracoscopic repairs have been described.^{29,30} A small rim of the internal transthoracic muscle is frequently found behind the sternum and is sutured to the diaphragm to close the hernia. We perform this closure with interrupted mattress sutures using a heavy nonabsorbable suture. Alternatively, the posterior rectus sheath or a rib can be used to help close the hernia. Rarely, the hernia cannot be closed without tension, and a patch is used.

Foramen of Bochdalek hernias can occur in adults. These are rare disorders that either are found incidentally on radiographs for other reasons or are recognized after

organ incarceration or volvulus.³¹ Most of these hernias are small and are repaired primarily. This can be performed with minimally invasive techniques. Larger defects may require a patch.

Congenital hernias can occur in each of the three central tendons of the trileaflet diaphragm and can be confused radiographically with tumors lying over the dome of the diaphragm. When the hernia occurs in the central trileaflet, it is frequently associated with a congenital absence of the inferior pericardial sac. This can lead to the phenomenon of abdominal contents within the pericardial sac. Repair of these hernias is straightforward because of the laxity of the central tendon. Primary repair is frequently possible. Very large defects may require patching.

The most frequent diaphragmatic hernia is the paraesophageal hernia. The most commonly used descriptive classification system defines four types of hiatal hernias. A sliding or type I hiatal hernia accounts for as many as 95% of paraesophageal hernias and involves the circumferential weakening of the phrenoesophageal ligament with symmetric displacement of the proximal stomach into the thoracic cavity. This is frequently associated with a shortened esophagus. Most type I hernias are asymptomatic and are discovered incidentally on radiographic studies or endoscopy. When symptoms occur, they are related primarily to the associated loss of lower esophageal sphincter tone and gastroesophageal reflux. The likelihood of these symptoms increases in proportion to the size of the hernia.³²

A paraesophageal or type II hiatal hernia involves a focal weakening of the phrenoesophageal ligament. These hernias tend to occur either anterior or lateral to the esophagus. The gastric cardia remains within the abdomen, and the lower esophageal sphincter remains at the level of the diaphragm. A portion of the gastric fundus, however, rolls through the defect into the chest and produces extrinsic compression of the lower esophagus.

A mixed or type III hiatal hernia has both a sliding and a rolling component. The lower esophageal sphincter has been displaced up into the thorax because of a shortened esophagus. A portion of the gastric fundus then rolls through the enlarged hiatal hernia, producing extrinsic compression of the distal esophagus as well. We agree with Pearson and colleagues³³ that a type II hernia with the gastroesophageal junction below the diaphragm is rarely seen, and type I and type III with the gastroesophageal junction displaced into the thorax are far more common.

Type IV hernias are associated with a large enough defect in the phrenoesophageal membrane to allow other organs, such as the colon, spleen, and small intestine, to enter the hernia sac and the chest cavity. Unrepaired type I, II, or III hiatal hernias can progress, resulting in a large defect between the crura of the diaphragm. As the hernia enlarges, the stomach has a tendency to migrate into the thoracic cavity. The positive pressure in the abdomen and the negative thoracic pressure can lead to the herniation of the greater curvature of the stomach into the right side of the chest and twisting of the stomach on itself. This gastric volvulus produces a gastric outlet obstruction. If

air or gastric juices distend the proximal stomach above the gastric outlet, the intraluminal pressure can exceed the perfusion pressure of the organ. This leads to ulceration, bleeding, and the potential for gastric rupture. Recognition of a gastric volvulus or displacement of intra-abdominal organs into the chest is an indication for urgent surgical repair. Because of this potential life-threatening complication, most surgeons recommend repair of these hernias even in the asymptomatic patient.

The initial step in operative repair of a hiatal hernia is to clearly delineate the muscular limits of the hiatal defect. Some experienced surgeons advocate a transthoracic approach for long-standing hernias to facilitate lysis of inflammatory adhesions under direct vision but at the cost of more postoperative pain. More recently, laparoscopic approaches have proved somewhat superior in this goal of identifying the limits of hiatal hernia because of the cephalad displacement of the diaphragmatic muscle during insufflation of carbon dioxide into the abdomen, making the two crura of the diaphragm taut. This tautness and extra space between the stomach and the diaphragmatic muscle greatly facilitate the dissection.

The fat between the proximal stomach and the diaphragmatic muscle needs to be removed. Dividing the muscular fibers of the left diaphragmatic crus in a straight lateral manner can enlarge tight hiatal rings. This will divide neither the branches of the phrenic nerve that lie far anteriorly nor the phrenic vein, which lies medially. The left inferior phrenic artery may be divided without causing ischemia because anastomosing vessels continue to perfuse the area. The enlargement of the tight hiatal ring can greatly facilitate the reduction of a large bulky hernia. Alternatively, a red rubber catheter can be passed across the neck of the hiatal hernia and air insufflated within the sac to facilitate reduction of the hernia contents. This breaks the natural vacuum that occurs in trying to reduce the abdominal contents through the hiatal neck.

The diaphragmatic defect needs to be closed as part of the surgical repair of the hiatal hernia. In fact, it is the pathologic process of the diaphragm that has contributed to the disease of gastroesophageal reflux by disrupting the lower esophageal sphincter. Closure of the dilated esophageal diaphragmatic hiatus is frequently performed by placement of sutures reapproximating the right and left crura of the diaphragm. In large hiatal hernias, this defect can be sizable. If the fibers of the diaphragmatic crura have been thinned, we frequently use pledgeted nonabsorbable sutures to reapproximate the right and left muscle bundles. The tenet of all hernia repairs is to prevent tension at closure, and some defects may require patch or mesh reinforcement. Two randomized studies comparing mesh with primary crural closure are available. Frantzides and colleagues³⁴ randomized 36 patients to closure with or without a polytetrafluoroethylene (PTFE) mesh onlay. At 3-year follow-up, 22% in the primary group had hernia recurrence compared with 0% in the mesh group. Another study with 50 patients used polypropylene rather than PTFE. The simple cruroplasty cohort had a 26% recurrence rate compared with 8% in the mesh group.³⁵

A late complication of the use of prosthetic mesh for this indication has been mesh migration and esophageal or gastric erosion, often ending in sepsis and the need for esophageal exclusion. Biological mesh options now exist that decrease the risk of this complication. The use of porcine small intestine submucosa has been described for closure of large hiatal defects.³⁶ This is now our preferred approach to reinforcement of the crura associated with giant paraesophageal hernias. A radial incision leading to a keyhole slit is made in the mesh to accommodate the esophagus, and the mesh incision is then closed with endoscopic placement of sutures. The material allows a remodeling of the hiatus and is eventually incorporated with the neighboring tissue so that a permanent material is not left in place.

The postoperative complication rate after laparoscopic antireflux surgery is approximately 8%. Between 3% and 6% of all patients undergoing antireflux surgery require reoperation for recurrent, persistent, or new symptoms secondary to complications of the initial repair.³⁷ In one published series of 627 patients, 7% of the entire group had demonstrable anatomic failure, most of which were the result of intrathoracic migration of the wrap with or without disruption of the fundoplication.³⁸ A number of factors have been attributed to this problem, including inadequate closure of the crura, lack of appreciation of a shortened esophagus, and physiologic factors that increase intra-abdominal pressure, such as the Valsalva maneuver, coughing, or retching in the postoperative period.

We believe that one of the most common errors in the surgical repair of hiatal hernias is not recognizing that an esophagus has shortened. If the esophagus is not of adequate length to allow the fundoplication to reside within the abdomen without undue pressure, the fundoplication will likely herniate into the thorax within a few years. We have a low threshold for extending the length of the esophagus with a Collis gastroplasty to ensure that the fundoplication will lie beneath the diaphragmatic hiatus without tension.

A rare but devastating complication of fundoplication herniation into the chest from an unrecognized shortened esophagus is a gastropericardial fistula³⁹ (Fig. 32-11). This rare condition has an associated mortality rate of more than 50% and is seen most often in patients with prior gastroesophageal surgery. It is most likely that these fistulas originate at the site of gastric ulcerations. Approximately 3% to 5% of open Nissen fundoplication procedures are complicated by gastric ulceration. In most cases, the ulcerations occur high on the lesser curvature of the stomach, in proximity to the fundoplication, and are seen most often in patients with recurrent hiatal hernias. Fistulas from the stomach to the aorta, diaphragm, pericardium, right ventricle, and bronchus have been reported as late complications from open Nissen fundoplication.³⁹

Repair of a gastropericardial fistula involves the removal of a circle of pericardium (see Fig. 32-11) and the fistulous entry into the stomach. The muscle of the diaphragm can then be used as a pedicled muscle flap to lie between the exposed heart and the staple line along the lesser curve of the stomach. In our experience, we

FIGURE 32-11 ■ **A**, Gastropericardial fistula is a devastating complication of a fundoplication herniating into the chest from failure to close the diaphragmatic crura. The fistula is typically along the lesser curve of the stomach distal to the fundoplication. **B**, This fistula was repaired by using the diaphragm as a muscle flap to place between the heart and the stomach. (From Murthy S, Looney J, Jaklitsch MT: Gastropericardial fistula after laparoscopic surgery for reflux disease. *N Engl J Med* 346:328–332, 2002.)

have used pledgeted sutures to close the muscles of the crura and secure the wrap beneath the diaphragm.³⁹

DIAPHRAGMATIC PACING

Diaphragmatic pacing may have a role to play for patients with compromised pulmonary function and diaphragmatic paralysis. The technology was first used clinically in 1967, and more than 700 patients with chronic hypoventilation have been treated in this manner, some

for as long as 18 years.⁴⁰ Expertise in this technique, however, is limited to a few centers. Technical details of long-term continuous pacing were mostly worked out by William Glenn of Yale. He and his colleagues rapidly moved from a successful animal model in 1964⁴¹ to treatment of a patient with central hypoventilation in 1967.⁴² Excellent detailed reviews of this subject have been published by Glenn and Koda⁴⁰ and Elefteriades and Quin,⁴³ also from Yale.

Diaphragmatic pacing has largely been supplanted by noninvasive methods of ventilatory support, including bilevel positive airway pressure and continuous positive airway pressure, particularly in the setting of temporary respiratory compromise or comorbid disease, such as chronic obstructive pulmonary disease. A select subset of patients, however, may be helped by this diaphragmatic pacing. The ideal patient for this technique has central nervous system or upper motor neuron disease and an intact phrenic nerve and diaphragm.^{43,44} The major experience with phrenic nerve pacing has come from quadriplegic patients and central alveolar hypoventilation patients. Patients with spinal cord injury above C3 are especially good candidates because the whole phrenic nerve is denervated from upper motor neurons but intact within the chest. Because pacing will not produce normal excursion of an atrophied diaphragmatic muscle, it is recommended that the pacemaker be placed soon after the neurologic insult.

The major therapeutic objective of diaphragmatic pacing is oxygenation rather than the elimination of carbon dioxide. Expiratory flow must be adequate, thus limiting the use of pacing in patients with severe chronic obstructive pulmonary disease or other conditions that have significantly altered the shape of the chest wall or diaphragm.⁴³ Sufficient diaphragmatic strength, almost normal function of the distal phrenic nerve, and satisfactory excursion of the thoracic skeleton must be demonstrated.

The topic of phrenic nerve pacing is frequently discussed in the setting of phrenic nerve palsy. The inherent lack of electrical conductivity of skeletal muscle, unlike the heart, does not allow uniform contraction of the muscle by multiple surface electrodes. An intact lower motor neuron (i.e., phrenic nerves) is thus required to deliver the electrical impulse by neurotransmitters throughout the muscle for coordinated contraction. Because axonal damage precludes conduction of electrical impulses to the neuromuscular junction, direct phrenic nerve injury is not amenable to pacing. These patients may be better treated with direct intervention (i.e., primary phrenic nerve repair or nerve transplantation with an intercostal or recurrent laryngeal nerve) or supportive measures (i.e., diaphragmatic plication, nocturnal bilevel positive airway pressure, or tracheostomy).⁴³

The best placement of the phrenic nerve pacemaker with current technology is within the upper thorax by an anterolateral thoracotomy through the third intercostal space. This allows placement of the electrode around the main phrenic trunk below the entry of the accessory nerve from the C5 nerve root, which frequently joins the phrenic nerve within the upper thorax.⁴⁵ It is important to avoid handling of the nerve because injury would

FIGURE 32-12 ■ Placement of phrenic nerve pacing lead to an intralateral thoracotomy. SVC, Superior vena cava. (From Kanaan S, Ducko CT: Disorders of ventilation: diaphragmatic pacing. In Fauci AS, et al, eds: *Harrison's principles of internal medicine*, ed 17, online update, New York, 2008, McGraw-Hill.)

prevent accurate pacing. The site of implantation of the electrode is above the azygos vein and superior vena cava on the right (Fig. 32-12).⁴⁴ In the left side of the chest, the preferred site is between the aortic arch and the pulmonary artery.⁴⁶ The wire attached to the electrode is then tunneled to the receiver in the chest wall. Although the nerve trunk is easily found in the neck, the phrenic nerve is missing the C5 accessory nerve at this level in 76% of patients.⁴⁷ Furthermore, placement of the electrode over the superior vena cava avoids direct conduction of the electrical signal to the atrium, which can occur lower in the thorax. Electrodes can now be placed thoracoscopically.⁴³ Implantation through the cervical approach has largely been abandoned because of its inability to bring the pacing electrode in proximity to the C5 branch of the phrenic nerve.

The phrenic nerve should be tested transcutaneously for patients with a central nervous system cause of hypoventilation to verify intact nerve and muscle function. This test was described by Shaw and colleagues in 1975.⁴⁸ An indifferent electrode is placed on the skin of the neck, and a pacing electrode delivering 5 to 10 mA for 1 msec is placed at the lateral border of the sternocleidomastoid muscle. A forceful contraction of the diaphragm signifies normal or almost normal diaphragmatic function. Forceful diaphragmatic movement can be observed by physical examination. Quantification of diaphragmatic excursion can be made by fluoroscopy or ultrasonography. An excursion of at least 5 cm should be seen for pacing intervention to be considered.^{43,44}

The initial diaphragmatic pacemaker consisted of a monopolar electrode attached to an antenna and a radio-frequency generator. A bipolar electrode would be used if the patient also has a cardiac pacemaker. To overcome the lack of natural electrical conductivity of the skeletal

muscle of the diaphragm, a train of pulse currents with increasing amplitude is delivered by the pacemaker to stimulate all axons within the nerve.⁴³ One consequence of the pulse train to induce uniform muscle contraction is that every fascicle is stimulated to contract. Because 24% of the fascicles are fast-twitch, fatigue-prone type IIB fibers,⁴⁹ full-time pacing can occur only after a period of muscle conditioning. Part-time pacing in quadriplegic patients does not start for 14 days so that pleural effusion can be avoided.⁴³ Pacing starts at 15 minutes per hour and changes every 7 to 14 days. Conditioning thus takes 3 to 6 months. A permanent tracheostomy is recommended for all patients on full-time, continuous phrenic nerve pacing.⁴³

Four pacing systems are available worldwide: the Avery model (Avery Laboratories, Glen Cove, NY), the Atrostim (Atrotech, Tampere, Finland), the Vienna Phrenic Pacemaker (MedImplant Biotechnisches Labor, Vienna, Austria), and the NeuRx Diaphragm Pacing System (DPS; Synapse Biomedical Inc., Oberlin, OH).⁴⁴ The first three models have a two-part system with an extracorporeal radiofrequency generator and implantable receiver-nerve electrode. Further technological improvements may make diaphragmatic pacing a more generalizable technique for patients with long-term but ultimately reversible dysfunction, such as viral palsies and iatrogenic injuries. The largest reported series of diaphragmatic implantation pacers observed 165 patients; 68% were paced for less than 5 years, 20% for 5 to 10 years, and 10% for 10 to 15 years.⁵⁰

Onders and colleagues⁵¹ have developed a separate diaphragm pacing system that can be implanted through a laparoscopic technique. For this form of pacing to be effective, an intact phrenic nerve is still required to recruit muscle contraction by conduction pathways. After laparoscopic ports are placed, the initial step is to map the diaphragm with a specially developed probe to see which point causes the greatest diaphragmatic excursion. Once this point has been identified, electrodes are placed on each side and retested. The lead wires are then tunneled to exit from the chest wall. Limited studies have shown results comparable to those of standard phrenic nerve pacing.⁵² Potential advantages compared with currently available phrenic nerve pacing include less expensive equipment and the ability to implant electrodes in both diaphragms without the need for repositioning or single-lung ventilation that is required during VATS procedures. Current experimentation with natural orifice transluminal endoscopic surgery may further decrease the invasiveness of this procedure and make temporary pacing in the intensive care unit a more realistic possibility.⁵³

At present, improved quality of life for patients is the reason for continued research into the science of diaphragmatic pacing. In addition to the obvious benefit of freedom from mechanical ventilation, pacing can also lead to improved speech patterns, conversion from tracheostomy to stoma devices, and return of olfactory sensation.^{44,46}

In summary, diaphragmatic pacing is useful for carefully selected patients with intact phrenic nerve and diaphragmatic muscle function but impaired upper motor

neurons. Results of unilateral pacing are not beneficial because the phrenic nerve is usually not functional. Patient selection and preoperative evaluation are crucial to successful, long-term diaphragmatic pacing.⁴⁴ The potential exists for a large group of patients with lower motor neuron disease (i.e., temporary or permanent phrenic nerve injury) to benefit once further advances in technology can produce smooth, coordinated muscle contraction of the diaphragm with direct muscle stimulation.

ONCOLOGY OF THE DIAPHRAGM

Primary tumors of the diaphragm are rare, and the literature is notable for scattered case reports only. Benign tumors include variants of fibrous tumors and lipomas, neurogenic tumors, and cysts. These tumors generally present as incidental findings on imaging studies, and most patients are asymptomatic. Surgical resection with primary closure or reconstruction is the standard treatment. Primary malignant tumors may arise from muscles, tendon, or mesothelial elements on either side of the diaphragm. Most of these lesions are sarcomatous in origin and are locally aggressive and best treated with complete diaphragmatic resection. The benefits of chemotherapy are limited. Because recurrence is usually local, various methods of irradiation delivered preoperatively or postoperatively have been used. We have also used intraoperative placement of brachytherapy seeds after resection of primary or secondary tumors of the diaphragm.

Invasion of the diaphragm from tumors on either side of the “fence” can occur. In the abdomen, this is most commonly seen with large retroperitoneal sarcomas, hepatocellular carcinoma, or upper gastrointestinal tumors, including direct extension into the hiatus by gastroesophageal junction adenocarcinomas.

Mesothelioma and chest wall sarcomas are thoracic malignant neoplasms that may involve the diaphragm and are discussed elsewhere in greater detail. Invasion of the diaphragm by primary lower lobe lung adenocarcinomas is considered T3 disease, and patients with T3 disease are often not considered for surgery on the basis of preoperative imaging because a corresponding pleural effusion is present that upstages the disease to T4. Others are given chemotherapy first to determine responders who will most benefit from surgery. Between 0.17% and 0.4% of patients are found to have diaphragm disease at explorative thoracotomy.^{54,55} Because of the rarity of this occurrence, limited data have been published about this topic. Weksler and associates⁵⁶ were the first to address this population of patients, describing eight patients between 1974 and 1995 who underwent exploratory thoracotomy for non-small cell lung cancer. All patients underwent en bloc resection with an overall survival of 52.8 weeks.

To improve on the limited data from the previous series, two multicentric retrospective studies have been done. Riquet and colleagues⁵⁶ reviewed 68 patients from 17 centers who underwent thoracotomy with resection of non-small cell lung cancer invading the diaphragm and found a 67% rate of lymph node involvement. This was

thought to be the result of the extensive lymphatic drainage of the diaphragm. Sixty-three patients in a study from the Lung Cancer Surgical Study Group of Japan were identified from 31 institutions. Complete resection was performed in 55 patients (87.3%), and the 5-year survival in these patients was 22.6%.⁵⁴ The depth of diaphragm involvement was noted to affect prognosis; patients with shallow invasion of the diaphragm had a 33% 5-year survival rate versus 14.3% in those with deep muscular or peritoneal invasion. The overall survival rate of these patients after complete resection compared with T3 lung cancers with chest wall involvement was significantly less.

DIAPHRAGMATIC RESECTION AND REPAIR WITH PROSTHETIC PATCH

Partial diaphragmatic resections are necessary to remove tumors that have invaded a portion of the diaphragm. The redundancy of the muscle frequently allows primary repair for small to modest resections. Larger defects are easily repaired with a mesh or impermeable graft sutured to the remnant of muscle. We use mesh for patients with lung tissue remaining in the ipsilateral hemithorax and impermeable grafts for patients who have had a pneumonectomy to prevent fluid shifts between the thorax and abdomen.

Complete diaphragmatic resection may be required for large tumors invading the diaphragm, such as lung cancer of the lower lobe or sarcomas of the chest. We have gained our extensive experience with complete diaphragmatic resection as part of an extrapleural pneumonectomy for mesothelioma.⁷

An extrapleural pneumonectomy is the complete removal of the pleural envelope and all its contents, including the ipsilateral lung, lateral pericardium, and underlying diaphragm. Because the pleura cannot be separated from the central tendon of the diaphragm, the diaphragm must be resected if the pleural envelope is to be kept intact during removal.

Diaphragmatic resection begins with traction of the pleura away from the chest wall deep into the diaphragmatic sulcus. This exposes the bare area of the lateral diaphragm where the pleura folds off the rib cage and back onto the upper surface of the diaphragm (Fig. 32-13).⁷ The division of these lateral radial bands of the fan-shaped portion of the diaphragm is started at the most anterior portion of the chest close to the pericardium. The fingers of the surgeon bluntly dissect the peritoneum from beneath the muscle, then pull the fibers taut to facilitate visualization to divide the muscle with cautery. It is not unusual for the posterolateral portion of the diaphragm to be beyond the direct vision of the surgeon. Fibers in this area can be bluntly avulsed with minimal risk of bleeding. Once the ligamentum arcuatum externum (external arcuate ligament) is reached in the paravertebral sulcus, the perinephric fat of Gerota fascia not the peritoneum, is directly beneath the fan-shaped muscle. This part of the dissection quickly progresses to the lateral margin of the crus. The diaphragm can then be separated from the peritoneum up toward the lateral

FIGURE 32-13 ■ Circumferential incision of the right hemidiaphragm exposing the underlying peritoneum. Pericardial and crural attachments remain after division of the fan-shaped muscle. (From Kanaan S, Ducko CT: Disorders of ventilation: diaphragmatic pacing. In Fauci AS, et al, eds: *Harrison's principles of internal medicine*, ed 17, online update, New York, 2008, McGraw-Hill.)

border of the pericardium. Defects in the peritoneum are closed as they are recognized.

An extrapleural pneumonectomy requires the removal of the lateral portion of the pericardium because the mediastinal pleura cannot be removed from that structure. The pericardium is opened anteriorly. The phrenic nerve is divided cephalad to the pulmonary artery. The trileaflet of the diaphragmatic tendon is divided along the line demarcating the central tendon of the ipsilateral muscle from the tendon lying beneath the pericardium. This cut is made medial to the insertion of the phrenic nerve into the anterior muscle. This medial cut is extended along the fused portion of diaphragmatic tendon and pericardium to the inferior vena cava on the right or the esophageal hiatus on the left.

At this point, the only attachment of the diaphragm remaining is the crus. Blunt dissection of the pleura of the deep diaphragmatic sulcus needs to be completed before division of the crus to prevent buttonholing of the inferior extent of the posterolateral pleura. The superior phrenic arteries are surgically inconsequential and rarely identified. The inferior phrenic vessels, however, lie on the deep surface of the crus and are easily seen and ligated. These vessels may bifurcate low over the crus, and a second branch may therefore be found after ligation of a branch thought to be the main trunk. The left inferior phrenic vein usually has two branches, one of which drains into the left renal or suprarenal vein and another that passes anterior to the esophageal hiatus and empties into the inferior vena cava. The right inferior phrenic vein empties directly into the inferior vena cava and therefore requires careful dissection and ligation. Vigorous lateral traction can avulse this vessel from the inferior vena cava, close to the insertion of the hepatic veins. Once these vessels have been divided, the crus is easily divided. This completes the diaphragmatic resection.

The postpneumonectomy space fills with fluid. To prevent fluid shifts between the thorax and abdomen, we use a 2-mm impermeable Gore-Tex prosthetic patch to reconstruct the resected diaphragm. This patch prevents herniation of abdominal contents into the chest, holds the abdominal viscera out of the thoracic irradiation field, and bolsters the contralateral diaphragm by fixing the medial edge of the fan into place. This then facilitates the function of the opposite diaphragm by allowing its central tendon to become the anchor point for the lateral fan fascicles. Without patching of the ipsilateral diaphragmatic defect, the contralateral muscle function is compromised.

After the patch has been cut to the shape of the removed diaphragm, the medial edge is sewn to the pericardial tendon with a soft nonabsorbable suture. We prefer 0 Ethibond for this suture. This suture line runs from the free edge of the divided anterior fan muscles, along the pericardial edge, to either the inferior vena cava or esophageal hiatus. A reliable lateral anchorage system has been devised, requiring a sterilized leatherworking awl (Fig. 32-14). Loops of suture material that have been passed through the lateral edge of the patch are then brought through the chest wall with the awl. The sutures are then passed through a small postage stamp-sized patch of the same material as well as a sterile polypropylene button, with the assistance of two angiocatheters. The loop of suture is then tied down to itself onto the button, resulting in excellent lateral displacement of the patch.

The posterior mediastinum between the thoracic spine and the inferior vena cava or esophagus is the area where patch ruptures occur, with abdominal contents herniating into the chest. This is the result of a lack of strong mediastinal tissue available to anchor the patch.

FIGURE 32-14 ■ Diaphragmatic resection for extrapleural pneumonectomy necessitates patch closure. A sterile leatherworking awl is used to pass anchoring sutures through the chest wall to re-create radial lines of tension. These sutures are secured along the outside of the rib cage with use of angiocatheters through the holes of sterile buttons.

Our group of surgeons have developed the following three potential solutions: (1) a suture anchoring the patch to the anterior spinal ligament, (2) a tongue of extra patch material folded inferiorly along the lumbar spine in simulation of the diaphragmatic crus, and (3) a composite of two patches of 2-mm Gore-Tex stapled together in the middle with a thoracoabdominal stapler to create a dynamic patch at the center with less tension at the lateral suture lines. The first technique uses the dense spinous ligament to anchor the posterior mediastinal portion of the patch and decreases the free defect between the anterior suture line at the inferior vena cava and the thoracic spine to a few centimeters. The second technique allows the medial portion of the patch to be partially displaced into the chest but prevents visceral herniation unless the entire tongue becomes displaced into the chest. The last technique allows the prosthetic patch to “give” without rupture if the patient experiences abdominal distention.

SUMMARY

The diaphragm serves several functions as a result of its unique anatomic location. It is the major muscle of respiration, by creating the intrathoracic vacuum and moving the lower ribs. It is a barrier between the positive-pressure abdomen and the negative-pressure thorax. It is important in the function of the lower esophageal sphincter.

Surgical approaches to the diaphragm are easily learned and depend on an understanding of the anatomy and physiology of the muscle, nerve, and blood vessels. Various incisions are possible once the locations of the nerve and vessel branches have been learned. These structures frequently lie within the muscle itself and are not seen on the surface of the structure. Therefore, the concept of a handcuff around the junction of the central tendon to the muscle is helpful.

Diaphragmatic repair and patching are helpful in traumatic injuries, congenital absence of a part of the diaphragm, and diaphragmatic hernias. Diaphragmatic pacing is not useful in phrenic nerve palsies because an intact lower motor neuron is required for the current level of technology to function. Plication of the diaphragm for these cases is useful. We prefer a radial plication technique that mimics the radial contraction of the fan-shaped muscle to that of a central tendon pleat.

Repair of gastroesophageal reflux depends on the construction of a new lower esophageal sphincter. A major contributor of the pathologic process, however, is a diaphragmatic hernia between the crura: a hiatal hernia. Therefore, we believe that tightening of the crus around the repair and lengthening of a shortened esophagus are important steps to keep the repair within the abdomen and to prevent complications such as gastropericardial fistula.

The entire hemidiaphragm can be resected. Small resections can be repaired primarily, but large resections should be patched to assist the function of the contralateral muscle. The choice between permeable and impermeable patches depends on the remaining presence of ipsilateral lung. The principles of the patch repair include

a tight apposition to the medial remnant of the diaphragm and then radial lateral displacement of anchoring sutures.

Although the diaphragm acts as a boundary between the thorax and abdomen, it should not serve as a boundary between the realm of thoracic surgeons and gastrointestinal surgeons. The diaphragm makes a good fence, but neighbors on both sides of that fence should know its anatomy, physiology, and surgical principles of resection and repair.

DEFINITION

Different congenital diaphragmatic anomalies include one or more defects that allow for herniation of abdominal contents into the chest. However, the term *congenital diaphragmatic hernia* (CDH), also referred to as *Bochdalek hernia*, refers specifically to congenital defects located on the posterior-lateral aspect of the diaphragm. Despite the name diaphragmatic “hernia,” there is a true hernia sac in only 15% to 20% of cases.

HISTORY

The first known written description of a diaphragmatic herniation was made by Ambroise Paré in 1579.¹ However, the two cases described by Paré were caused by trauma. In his *Sepulchretum* of 1679, Teophile Bonet attributed the first description of a congenital case to Lazare Rivere at the beginning of the seventeenth century,

even if from the necropsy of an adult.² The first report of a CDH in a newborn was made by George Macaulay in 1754, also as a necropsy finding, in an infant who died from respiratory failure a little over 1 hour after birth.³

In 1761, Giambattista Morgagni, then a pupil of Valsalva, wrote a review of diaphragmatic herniations and credited Stehenius with the first observation that CDH was associated with pulmonary hypoplasia.⁴ In the review, Morgagni described the first case of a parasternal hernia in an older man, henceforth termed *Morgagni hernia*. In 1848, Vincent Alexander Bochdalek reported two cases in which he described the location of the diaphragmatic defect as being in the posterior-lateral aspect of the muscle, hence the origins of the terms Bochdalek hernia and Bochdalek foramen.⁵ Although widely used, these terms are actually improper given that the mechanisms and exact location proposed by Bochdalek, namely “rupture of the lumbocostal triangle,” are inaccurate.⁶⁻⁸

The link between CDH and deviations of the embryonic development of the pleuroperitoneal membrane only started to be established from the studies by Broman

in 1902 and 1905.^{9,10} Nevertheless, although this anatomic location for the diaphragmatic defect is universally accepted, it is not yet known where the primary disorder that leads to CDH takes place.

The first successful repair of a CDH was performed by Aue in a 9-year-old boy in 1901, but published only in 1920.¹¹ The first publication of a successful CDH repair was by Hedenhain in 1905; he reports a procedure, also in a 9-year-old boy, occurred in 1902.¹² In 1940, the first survival of a neonate, who underwent CDH repair on the second day of life, was reported by Ladd and Gross.¹³ Gross was also the first to report on a good outcome after repair before the first 24 hours of life, in 1946.¹⁴

In 1977, German and colleagues¹⁵ reported the first child with CDH to survive after being placed on extracorporeal membrane oxygenation (ECMO). Ever since the mid-1980s, it has become clear that ECMO plays a major role in maximizing the survival rates of neonates with CDH.¹⁶⁻¹⁸

In 1989, Harrison presented the first series of CDH treated by open prenatal repair of the diaphragmatic defect in humans, leading to live births but no midterm survival.¹⁹ Survival after this procedure was reported by this same group in 1992, but only in 28.6% of the operated fetuses.²⁰

In the early 1990s, from the work of Wung and coworkers, the concept of avoiding hyperventilation and minimizing barotrauma was introduced.^{21,22} These principles have since led to marked reduction in iatrogenic insult to the lungs, which was common in the old, aggressive ventilation strategies, and consequently significant improvement in survival.^{16,23-25}

The first successful lung transplantation for the treatment of CDH was performed in a newborn in 1992, by the groups of Shochat and Starnes.²⁶ Also in 1992, Wilson first showed, in an ovine model of CDH, that fetal lung growth could be significantly accelerated after occlusion of the fetal trachea, leading to reversal of the pulmonary hypoplasia associated with experimental CDH.²⁸ In 1994, Harrison's group first applied this maneuver successfully in a human fetus with CDH.²⁹ Nonetheless, the results of fetal tracheal occlusion, be it done open or videofetoscopically, remain worse than those of postnatal care, at least at the referral centers in North America.³⁰⁻³² Still, fetal tracheal occlusion continues to be offered systematically at a few European centers and anecdotally elsewhere, though its current indications, if any, remain to be clearly defined.^{33,34} A prospective randomized trial of fetal tracheal occlusion (TOTAL) is currently underway in Europe.

In 1994, the Congenital Diaphragmatic Hernia Registry was created, as a meta-institutional organization dedicated to the exchange and analysis of data related to this disease, as well as to the design and implementation of multicentric prospective trials. This initiative was molded after the pediatric oncology groups first established in the 1980s and, as such, has had a major beneficial impact on CDH survival and management guidelines.³⁵

In 1995, we demonstrated experimentally that lung growth could also be accelerated after birth, through

continuous intrapulmonary distention with a perfluorocarbon.^{36,37} The first series of patients that received this treatment, under ECMO support, was presented in 2000.³⁸ A multicentric prospective trial of this principle has proven difficult to pursue due to regulatory and logistical hurdles, yet it remains an anticipated perspective. Also in 2000, the use of a tissue engineered construct for the repair of the diaphragmatic defect was first proposed in an animal model.³⁹ Further experimental developments have validated engineered diaphragmatic repair and a clinical trial is expected in the not too distant future, pending regulatory clearance.⁴⁰⁻⁴⁴

In general, current development efforts are aimed at further refining pre- and postnatal prognostic markers, defining the patients that would benefit from lung growth acceleration (whether pre- or postnatal), enhancing diaphragmatic repair through tissue engineering, and minimizing morbidity of the increasingly more common long term survivors.

EPIDEMIOLOGY

The prevalence of CDH has been reported as being anywhere between 1:1,200 and 1:12,000 births.⁴⁵⁻⁵⁴ Likely, the main reason for such disparities is the so-called hidden mortality of CDH, which relates to the fact that many babies die before making it to a referral center and thus are not included in the statistics. The better controlled studies show CDH as occurring in 1:2,107 to 1:3,163 births.^{45,47-50,52} One of the largest series ever studied, by Torfs and colleagues,⁵² involving over 718,000 births and stillbirths in part of California, revealed that CDH occurred in 1:3,163 births and in 1:3,340 live births. Among the major congenital anomalies, CDH is one of the most common, accounting for approximately 8% of the cases.⁵⁵

There are no clear racial differences in the prevalence of CDH.^{50,52} The study by Torfs and colleagues⁵² showed a higher prevalence in rural rather than urban areas, but this has not yet been confirmed by other series. The prevalence of prematurity and weight deviations in neonates with CDH is no different from that of the general population.⁵² While isolated CDH is a little more common in boys than in girls (1.5:1), sex distribution is normal in CDH associated with other congenital anomalies and in the whole CDH population.^{52,56}

There is limited controversy as to the risk of CDH recurrence within families. In the vast majority of cases, CDH is sporadic, with no genetic component described to date and with the risk for further offspring being practically equal to that of the general population.^{45,47} At the same time, many families with more than one case of CDH, usually siblings, have been identified.^{48,52,55,57-63} Less frequently, relatives other than siblings can also present with this anomaly.^{58,64,65} The epidemiologic profile of familial cases of CDH differs little from that of the total of cases: it is slightly more common in males (approximately 2:1)^{57,60,64} and there is conflicting data as to the other variables.^{59,65} The occurrence of familial CDH follows a pattern suggestive of multifactorial inheritance as the most likely mode of transmission, with

recurrence estimated between 1.3% and 2%.^{52,55,59,62} The possibility that a genomic imprinting phenomenon takes place has also been proposed.⁶³ A somewhat recent extensive review of a single hospital-based malformation surveillance program (the largest to date of consecutively collected cases of CDH) showed low recurrence among siblings.⁶⁶

EMBRYOLOGY OF THE DIAPHRAGM

The diaphragm comes from the mesoderm. Its development is complex and not yet fully understood. It results from the fusion of four embryonic components: two odd ones, namely the transverse septum and the mediastinum (also known as the dorsal mesentery of the esophagus), and two paired structures, namely both sides of the body wall musculature and both pleuroperitoneal membranes⁹ (Fig. 33-1).

The diaphragm begins to develop during the 3rd and 4th weeks of gestation, with the appearance of the first component of the diaphragm, the transverse septum (see Fig. 33-1). At this point, the transverse septum is an incomplete mesenchymal divider, related cranially to the pericardial cavity and caudally to the midgut. Dorsally, the transverse septum blends with the mediastinum. On each side of the mediastinum there are the pleural canals, which connect the pericardial and peritoneal cavities. The subsequent development of the diaphragm depends on the closure of these dorsal pleural canals, which will give rise to the pleural cavities.

During the 4th week, the pulmonary buds, which are developing inside the mediastinum, begin to protrude into the pleural canals. At this stage, the pleural canals are very small and the pericardial cavity is very large. Crests formed on both extremities of the pleural canals will separate the future pleural cavities from the pericardial cavity, cranially, and from the peritoneal cavity, caudally. The cranial crest will give rise to the pleuropericardial membrane and the caudal crest will form the pleuroperitoneal membrane (see Fig. 33-1).

FIGURE 33-1 ■ The four embryonic components of the diaphragm. A, Aorta; E, esophagus; IVC, inferior vena cava.

The enlargement of what are now the pleural cavities leads to a progressive narrowing of the opening between them and the pericardial cavity, as well as to the development of the pleuropericardial membrane. In like manner, there is progressive narrowing of the pleuroperitoneal canals and the development of the pleuroperitoneal membranes.^{6,7} The definitive closure of the pleuroperitoneal canals, now small, will occur during the 8th week of gestation.⁶

After closure of the pleuroperitoneal canals, the pleural cavities continue to expand, in parallel to lung growth. Cranially, they spread out beyond the limits of the pericardial space. Caudally, they extend into the body wall.⁶ During this process, which takes place from the 9th to the 12th week, the mesoderm in the posterior thoracic wall is carved by the caudal borders of the expanding pleural cavities, so that its inner portion will become part of the diaphragm. At the same time, a similar process happens at another, more lateral and anterior portion of both the thoracic and the abdominal walls. As a consequence, part of the diaphragmatic muscle originates from the musculature of the thoracic and the abdominal walls.^{6,67}

Despite the almost universal acceptance of this explanation for the development of the diaphragmatic muscle, there is some controversy related to the role of the phrenic nerve in that process. In accordance with the principle that muscles in general retain their original segmental innervation, certain authors believe that myoblasts derived from the caudal portion of the infra-hyoid mesoderm migrate, together with the phrenic nerve, from the third and fourth cervical somites, towards the diaphragm, so that this would be the origin of the diaphragmatic muscle.^{68,69} However, the phenomenon of myoblast migration together with the phrenic nerve has not yet been proven; it is but a partially accepted theory. The fact that the tendinous center of the diaphragm is a fibrous structure completely devoid of muscle fibers speaks against this theory.⁷ In any event, even if myoblasts from the superior cervical myotomes do follow the phrenic nerve, at least part of the diaphragmatic innervation should be later transferred to muscular portions derived from the thoracic and abdominal walls.

Deviations from the normal development of each one of the various components of the diaphragm bring about different variants of diaphragmatic anomalies. Table 33-1 shows the diverse embryonic origins of the diaphragm and their relation to different diaphragmatic defects.

PATHOLOGY

Etiology

The etiology of CDH is unknown. In a few rare syndromes in which a diaphragmatic defect is present is there a well-defined genetic cause, such as in trisomies of the chromosomes 13 and 18. On the other hand, a single institution review showed that 17% of all cases of CDH (i.e., both isolated and in association with other congenital anomalies) had a recognizable genetic etiology.⁶⁶ In addition, there was no concordance for CDH among five

TABLE 33-1 Embryologic Origins of the Diaphragm and Corresponding Diaphragmatic Defects

Embryonic Structure	Time (wk)	Portion Formed	Diaphragmatic Defect
Transverse septum	3 and 4	Central tendon	Pericardial hernia (ventral defect)
Pleuroperitoneal membranes	7 and 8	Primitive diaphragm	Bochdalek hernia (posterolateral defect)
Mediastinum (dorsal mesentery)	—	Median portion and crura	—
Body wall	9-12	Muscle periphery (ventral-lateral and dorsal)	Morgagni hernia (parasternal defect) and eventration

monozygotic twin pairs. These findings, in conjunction with previous reports of *de novo* dominant mutations in CDH patients, suggest that new mutations may be an important mechanism in the etiology of this disease. At the same time, the discovery of CDH loci using standard methodology has been hindered by the genetic heterogeneity of this disease. Relatively novel techniques such as array comparative genomic hybridization, whole-transcriptome expression profiling, and whole-exome sequencing, among others, are now being pursued and already shedding new light upon the extent and relevance of specific genetic abnormalities associated with CDH.⁷⁰⁻⁷⁵

Even so, the twin data also point to the possibility that epigenetic abnormalities contribute to its development. Indeed, experimental CDH can be produced in diverse animal species through a variety of interventions, other than surgical creation of the defect, including: exposure to diet deficient in either vitamin A,^{76,77} zinc,⁷⁸ or cadmium⁷⁹; administration of either thalidomide,⁸⁰ anti-rat rabbit serum,⁸¹ 2,4-dichlorophenyl-p-nitrofenilic ether (nitrofen, an herbicide),⁸²⁻⁸⁴ or polibromate biphenils^{85,86}; induction of endothelial heparan sulfate deficiency⁸⁷; and genetic manipulations, such as FOG-2, COUP-TFII, GATA-4, SOX7, and Slit3 mutations.⁸⁸⁻⁹² However, to date, there's been no conclusive relationship between these experimental models and clinical/epidemiological data in humans.

Pathogenesis

The pathogenesis of CDH is also unknown. Normally, before the return of the bowel from the umbilical cord to the abdominal cavity, which occurs during the 10th week of gestation, it is necessary for the pleuroperitoneal canal and the lumbocostal triangle to firmly close, which happens between the 8th and 10th weeks. In case such closure does not take place, the bowel will pass through the pleuroperitoneal canal, sometimes also through the lumbocostal triangle, and will invade the chest, resulting in a "herniation" without a hernia sac. In case there is only a membranous closure, the same phenomenon will happen, albeit with a hernia sac that may, or not, rupture sometime later. In any case, although it is well established that the diaphragmatic defect is at the level of the pleuroperitoneal canal,^{6,7,9,10} the sequence of events that culminates in disturbances of its closure remain to be determined.

The prevailing theory as to CDH development has been that the incomplete closure of the pleuroperitoneal canal was a primarily diaphragmatic defect and that the abdominal viscera herniated to the thorax impeded

normal lung development and resulted in the pulmonary hypoplasia and hypertension observed almost universally in association with CDH. This perception was widely confirmed by animal models in which a diaphragmatic defect was surgically produced in fetuses of different species,⁹³⁻⁹⁵ or in which the diaphragmatic herniation was mimicked by an inflatable prosthesis placed in the pleural cavity.⁹⁶ All these models resulted in lung hypoplasia and pulmonary hypertension at birth.

Nonetheless, the foremost notion today is that the primary defect is not in the diaphragm, but in the lung buds, and that the diaphragmatic defect would actually be secondary to a primary pulmonary hypoplasia. Such pulmonary hypoplasia, in turn, could be intensified even more by the presence of abdominal viscera herniated into the chest. Starting at the 4th week of gestation, the growth of the pulmonary buds and of the pleural cavities result in a progressive narrowing of the pleuroperitoneal canals and in the formation of the pleuroperitoneal membranes.^{6,7} The development of the diaphragm, more specifically of the pleuroperitoneal membranes, is intimately related to lung development itself. Researchers that have worked with the experimental model of CDH induced by nitrofen have shown that, in that model, the pulmonary hypoplasia precedes the diaphragmatic defect.^{83,84,97,98} These findings are in accordance with the fact that nitrofen exposure can lead to pulmonary hypoplasia independently of the existence of CDH.⁹⁹⁻¹⁰¹ Iritani⁸³ has concluded that the lung buds, which are primarily hypoplastic because of the exposure to nitrofen, cause hypoplasia of the post-hepatic mesenchymal plate, which in turn develops in intimate association with the lung buds. The hypoplasia of this mesenchymal plate, which is one of the precursor portions of the primitive diaphragm, would then give rise to the diaphragmatic defect and, consequently, the CDH.⁸³ Moreover, it is thought that the morphogenesis and differentiation of the pulmonary respiratory epithelium is intimately dependent on the kind of extra-cellular matrix synthesized by the mesenchyme.^{84,102,103} Kluth and colleagues¹⁰³ have shown that lungs of embryos exposed to nitrofen display an abnormal expression of factors normally found in the extracellular mesenchymal matrix, with a delayed pattern of epithelial differentiation. Iritani speculates further that the fact that CDH is more common on the left in humans is because lung bud development tends to be slower on the left than on the right.^{83,104,105} and, also, the fusion of the pleuroperitoneal membranes happens later on the left side than on the right.⁹³ Independently of the possibility of a primary pulmonary hypoplasia in the nitrofen model, Alles and colleagues¹⁰⁶ have shown that there is also cell death in the mesoderm of some cervical somites which are

precursors of the diaphragm, suggesting a concomitant primary disorder of diaphragmatic development. Consequently, the mechanism behind the emergence of CDH in this model is still to be clarified.¹⁰⁶ Knock-out models, such as FOG-2^{-/-} mice, are also further evidence of a primary pulmonary hypoplasia associated with CDH.⁸⁹

The possibility of a primary endothelial defect in the diaphragm and/or the lungs being a culprit has been suggested more recently, for example from the observation that experimentally induced heparan sulfate deficiency disrupts developmental angiogenesis and leads to CDH, at least in mice.⁸⁷ The identification of parathyroid and thymic anomalies related to embryonic neural crest dysfunction in a rat model, as well as in human infants with CDH, have pointed to a potential involvement of neural crest dysregulation in the pathogenesis of CDH, which however remains to be better recognized.¹⁰⁷ A so-called “smooth muscle hypothesis,” pointing to abnormalities in airway smooth muscle development as central to the pathogenesis of CDH has also been proposed, but not yet fully validated.¹⁰⁸ There are still a number of other, less accepted theories for the pathogenesis of CDH.^{69,109-111} Whichever the location and nature of the primary defect may be, the presence of a diaphragmatic defect *per se* usually leads to herniation of abdominal viscera to the chest, which, in turn, at least contributes to worsening the pulmonary hypoplasia.⁹³⁻⁹⁵ The sooner the herniation occurs in gestation and/or the larger the herniation content, the more intense the pulmonary hypoplasia tends to be.

Pathologic Anatomy

Gross Findings

The diaphragmatic defect, or Bochdalek foramen, is located in the posterior-lateral aspect of the diaphragm, involving at least the area that would have originated from the pleuroperitoneal membrane and, many times, also the area immediately posterior to it, namely the lumbocostal triangle (Fig. 33-2). The size of the defect is highly variable, from less than 1 cm in diameter, to an

FIGURE 33-2 ■ Typical intraoperative finding, through a left subcostal laparotomy, in a neonate with congenital diaphragmatic hernia. Note the defect on the posterolateral aspect of the left diaphragm.

almost complete absence of the hemi-diaphragm, extending beyond the dome, practically to the midline, preserving merely a small anterior-lateral band of muscle. There is no fibrosis or any evidence of inflammation at the level of the diaphragmatic opening. The left side is affected in approximately 80% to 90% of the cases, the right side in 10% to 20%, and bilateral cases are rare, occurring in approximately 1% of the patients.^{17,112}

In most cases, the pleura and the peritoneum are in continuity over the borders of the diaphragmatic defect, which may render the identification of the residual posterior muscle band difficult. In only approximately 15% of the patients is there a hernia sac. The size of the diaphragmatic opening does not necessarily relate to the volume of the herniation.

Because of the herniation to the chest, the mediastinum is usually deviated to the contralateral side of the hernia (Fig. 33-3). Both lungs, but particularly the one ipsilateral to the defect, are smaller than normal in both volume and weight (Fig. 33-4).¹¹³⁻¹¹⁵ Pulmonary lobulation is ordinarily normal, but may be compromised in a few cases.^{113,116} On the other hand, the shape of the pulmonary lobes is commonly distorted.^{113,116} The pulmonary ligament is almost always absent on the side of the hernia.¹¹³ The number of airway generations and their dimensions are reduced, especially in the ipsilateral side of the defect.^{113,116} The pulmonary arteries, as well as the number and dimensions of their branches, are smaller than normal, in proportion to the reduced size of the lungs, also particularly on the side of the hernia.¹¹³

FIGURE 33-3 ■ Typical gross autopsy finding from a neonate with congenital diaphragmatic hernia. Note the abdominal organs herniated to the left hemithorax through the posterolateral defect on the ipsilateral diaphragm, and the mediastinal deviation to the right. There is no hernia sac.

FIGURE 33-4 ■ Thoracic cavity in the neonate shown on Figure 33-3, after removal of the abdominal organs herniated to the left hemithorax. Note the reduced size of the lungs, especially on the left.

The herniation of abdominal contents to the thorax and the pulmonary hypoplasia may both lead to the appearance of many other abnormalities. Because of that, such abnormalities are not exactly considered other anomalies associated with CDH, but actually integral components of the so-called “CDH syndrome.”¹¹⁷ The most frequent of such abnormalities are: persistent *ductus arteriosus*, persistent foramen ovale, and intestinal malrotation.¹¹⁷ Less frequently, the following abnormalities can also be a direct consequence of CDH: gastric volvulus, abnormally sized chest cavity, accessory spleen and/or congenital splenic fibrosis in left CDH, abnormal hepatic lobulation and/or hepatopulmonary fusion in right CDH, and hypoplasia and/or fibrosis of the lobe of the liver ipsilateral to the hernia.¹¹⁷⁻¹¹⁹ Also, expectedly, the volume of the abdominal cavity is frequently reduced.

Microscopy

Except for the defect itself, the diaphragm does not exhibit any other deformity. A local decrease of the density of branches of the phrenic and intercostal nerves has been described by some,⁶⁹ but not yet confirmed by others and is considered of limited value.¹⁰⁶

The impact of CDH on the lungs varies within an ample spectrum. The lung ipsilateral to the hernia is impaired the most, but both lungs are affected. In a given patient, the effects of the hernia are not uniform on the different portions of each lung.

The airway branching order is abnormal, with a reduced number of generations of lower bronchi and bronchioli, often with complete absence of the latter, so that bronchi may end directly in alveoli.^{113,115,116} Given that normal airway branching is complete by 16 weeks of gestation,^{104,120} the reduction in airway generations observed both grossly and microscopically is further evidence of the fact that CDH and/or pulmonary hypoplasia start before this time, more specifically between the 10th and 12th weeks. On the other hand, the development of airway cartilage itself does not seem to be affected, so that

the proportion of cartilage-bearing airways to the total number of airways is normal.^{113,116} Yet, the number of bronchi containing mucous glands is diminished.¹¹⁶

The total alveolar number is reduced, both in absolute terms, as well as in relation to total lung volume.^{113,115,116} However, the number of alveoli per acinus may be either reduced or normal, suggesting that the reduction in total alveolar number is mostly a consequence of the lower number of terminal bronchioli.^{113,115} The alveoli are also smaller than normal.¹¹³ The fate of type II pneumocytes is not yet completely clear. Many studies uncover evidence that the surfactant system is depressed, but it is not absolutely clear whether this has to do with a reduction in the density of type II pneumocytes, or not.¹²¹⁻¹²⁷ Defects in bronchopulmonary innervation have also been identified.¹²⁸

In parallel to the lower number of airway generations, the absolute number of arterial branches is reduced,¹¹³ yet the density of intra-acinar arteries may be normal.¹¹⁵ The arterial diameters are reduced.^{113,115} There is hypertrophy of the arterial muscle layer at all levels, as well as extension of such muscle layers into more distal branches, which normally would not bear any muscle.^{113,115,129,130} There seems to be a direct relationship between pulmonary hypoplasia and arterial muscularization, so that the more hypoplastic the lung, the more intense is the abnormally augmented muscularization.¹²⁹ Abnormal pulmonary lymphatic development has been identified in experimental CDH, but remains to be definitely described in human infants.¹³¹

Pathophysiology

The cardinal aspects of CDH pathophysiology are pulmonary hypertension with persistence of a fetal circulatory pattern, along with a reduction in both pulmonary tidal volume and compliance. The intensity of such manifestations varies a great deal, going from almost nonexistent to incompatible with life, depending mostly on the severity of the anatomical abnormalities of a given patient. According to some, a deficiency of the surfactant system is also part of CDH pathophysiology.¹²¹⁻¹²⁴ However, this notion has been increasingly challenged by more recent data.^{127,132,133}

In children, total peripheral airway cross section area is proportionally larger than in adults, hence the reduction in airway generation present in CDH usually does not lead to significant increases in airway resistance.¹³⁴ The difficulty in ventilating children with CDH stems mostly from the lower pulmonary compliance and lower tidal volumes. The pressure-volume curves of these hypoplastic lungs are abnormal, so that, at a given pressure, lung volume is lower than normal.¹³⁵ Microscopic analyses under insufflation show that, while certain airspaces may open at 15–20 cm H₂O, many are still closed at 30–35 cm H₂O.¹³⁶ Thus, higher inspiratory pressures are transferred only to the alveoli that are open, leading to alveolar rupture and a tendency to develop pneumothorax.¹³⁷ It is not yet clear whether the decreased pulmonary compliance is a result of a quantitative and/or qualitative depression of the surfactant system, or a relative increase in the total amount of collagen in the

lungs.^{121-123,138} The lower tidal volumes are a direct consequence of the reductions in both lung volume and total alveolar number.¹¹³⁻¹¹⁶ All these ventilatory abnormalities are the main reasons for the tendency of infants with CDH to retain CO₂.¹³⁷

Contrary to what happens with the airways, the peripheral vessels (lower arteries, arterioles, and capillaries) account for most of the pulmonary vascular resistance (PVR). Therefore, as a result of the reduction in the total number of arterial branches and their lower than normal diameters, the total arterial cross sectional area is diminished and the PVR is usually significantly increased in CDH.^{139,140} Further contributing factors to the increased PVR are the hypermuscularization of the arteries and amplified arterial reactivity. Because of the latter, certain physiological stimuli such as alveolar hypoxia, hypoxemia, hypercapnia, acidosis, cyanosis, hypothermia, as well as any “disturbances,” such as certain inflammatory mediators and simple manipulations of the patient, may trigger intense pulmonary vasoconstriction and marked increase in PVR.^{141,142} Other than the possibility of a role played by the muscular hypertrophy present in pulmonary arteries and arterioles, the reason why these vessels tend to overreact to stimuli is not yet known. Recent data suggest that the pulmonary vasculature’s ability to synthesize nitric oxide is depressed in CDH and thus may be part of the mechanism.¹⁴³ The possibility of an imbalance involving prostanooids, which are vasoactive agents that include prostaglandins, playing a role has been suggested.^{140,144-146} A potential role for other endogenous vasoactive agents, such as endothelin, in the increase in PVR has proved debatable.^{140,147,148}

This increase in PVR leads to pulmonary hypertension, which is almost universally observed in neonates with CDH.^{136,140,149} Pulmonary hypertension leads to a decrease in total blood flow to the lungs, an increase in end-diastolic pressure in the right ventricle, and a tendency for persistence of a fetal circulatory pattern, with right-to-left shunt through the ductus arteriosus and foramen ovale.^{136,141} The decrease in total pulmonary blood flow and the right-to-left shunt lead to hypoxemia, hypercapnia, and acidosis, which in turn are stimuli to pulmonary vasoconstriction, which worsens the pulmonary hypertension, with consequent intensification of the fetal circulatory pattern and so forth, establishing a vicious circle difficult to break. Not infrequently, patients may be satisfactorily oxygenated and fairly stable, until a random stimulus, or nothing immediately discernible, triggers the vicious circle of fetal circulation. Such a period of temporary stability that precedes the emergence or worsening of pulmonary hypertension has been coined *honeymoon*. It was described for the first time by Collins and colleagues^{140,150} in the mid-1970s and remains a frequent observation in neonates with CDH. The mechanisms responsible for the end of the honeymoon have been elusive until the last few years, when mounting evidence points to it being a cardiac event, more specifically variable degrees of right heart failure.¹⁵¹ Patients who present soon after birth with persistent hypoxemia, without ever going through a honeymoon period, usually have severe pulmonary hypoplasia and serious abnormalities of the pulmonary vasculature.¹³⁰

In the fetus, the oxygenated blood that comes from the placenta returns to the right heart through the umbilical vein and crosses either the foramen ovale or the ductus arteriosus toward the aorta, so that only approximately 7% of the cardiac output goes through the lungs.¹⁵² Therefore, the hemodynamic disturbances associated to pulmonary hypertension almost never manifest in utero. After birth, however, the hemodynamic status tends to deteriorate, often with overload and potential failure of the right heart. Thus, cardiac failure is typically part of the pathophysiology of CDH^{151,153,154} and survival depends, to a great extent, on the ability of the myocardium to withstand the overload imposed by the pulmonary vasculature.^{136,151,153} The deviation of the mediastinum by the herniated content may lead to a decrease in the venous return to the heart, possibly contributing to further worsening of the patient’s hemodynamic status.

It has been suggested that neonates with CDH may have adrenal insufficiency, with an inadequate response to stress.¹⁵⁵ At the same time, there is preliminary experimental evidence pointing to the possibility that lower than normal glucocorticoid levels can contribute to the abnormal lung development and maturation found in CDH.¹⁵⁶ The true meaning of these findings in CDH pathophysiology remains to be better defined. Indeed, at least as far as receptors are concerned, hypoplastic lungs of fetuses and newborns with CDH seem to be as responsive to glucocorticoids, thyroid hormone, and retinoic acid (all relevant to normal pulmonary development) as the lungs of normal children.¹⁵⁷

Among the different aspects of the pathophysiology of CDH, it is the pulmonary hypertension that is most responsible for mortality in the neonatal period. Since otherwise healthy neonates who undergo total pneumonectomy are often able to maintain good oxygenation and ventilation, without clinically relevant pulmonary hypertension, the lack of pulmonary parenchyma alone cannot explain all the manifestations commonly observed in infants with CDH.¹⁵⁸ Rarely in CDH is the bilateral lung impairment intense enough to cause a neonate to have less than half of the normal total alveolar surface area. Consequently, it would appear that, more often than not, the pulmonary vasculature abnormalities are clinically much more relevant than the lack of alveoli (pulmonary hypoplasia).

CLINICAL MANIFESTATIONS

Approximately 90% of the patients with CDH are symptomatic within the first 24 hours of life.¹⁵⁹ Yet, this disease can first manifest at any age and, more rarely, go unnoticed until late in life, or even never be diagnosed.¹⁶⁰⁻¹⁶²

When a child is symptomatic within the first 24 hours of life, the main clinical manifestation is respiratory distress. The earlier the onset of signs and symptoms, the more severe the pulmonary disease. Newborns that are symptomatic in the first 6 hours after birth are considered high risk and account for 88% of the cases.¹⁵⁹ Tachypnea associated with sternal, subcostal, and supraclavicular retraction is common. Cyanosis and pallor are also frequent. Apgar scores tend to be low. If untreated, the

dyspnea tends to worsen over time for three reasons: the progressive distention of the intrathoracic bowel by gas, which is accelerated by aerophagy, common in children in respiratory distress; the gradual increase of the volume herniated to the chest, which is a result of the negative pressure exerted during respiration; and the escalating hypoxemia, hypercapnia, and acidosis because of the vicious circle generated by persistent pulmonary hypertension. The abdomen is often scaphoid because of the migration of abdominal viscera to the chest. However, because of possible bowel distention inside the abdominal cavity, the abdomen can assume a normal appearance over time. The chest may be asymmetrical and larger on the side of the hernia, especially after the bowel fills with gas. The heart sounds are commonly dislocated to the contralateral side of the hernia. Sometimes, the same happens with the trachea. In the ipsilateral hemithorax, the respiratory sounds may be diminished or absent altogether, while bowel sounds may be present. There may be hemodynamic instability, with a tendency to arterial hypotension, because of a decreased venous return to the heart due to the mediastinal deviation and/or because of right heart failure due to pulmonary hypertension. Occasionally, mediastinal deviation can also lead to superior vena cava syndrome.¹⁶³ If it goes untreated, a symptomatic newborn usually dies within a few minutes or hours.

Rarely in the neonatal period, there are manifestations stemming from perforations or strangulation of a hollow viscus, gastric or midgut volvulus, or rupture of a herniated spleen, such as gastrointestinal obstructions, empyema, hemothorax, fever, arterial hypotension, coagulopathy, anemia, or hypovolemic shock. Anecdotal associations between CDH and septicemia with group B streptococcus in premature babies have also been described.¹⁶⁴

When CDH first manifests after the neonatal period, partial or complete gastrointestinal (GI) obstructions are more common than respiratory distress, which, if at all present, tends to be mild. Unlike in the neonates, the spectrum of manifestations of late presentation CDH is broad, including (in addition to GI obstruction and respiratory distress) sudden death, growth retardation, perforations or strangulations of intrathoracic hollow viscus (which can lead to sepsis, empyema, pneumothorax, or hemothorax), rupture of a herniated spleen (with hemothorax, anemia, and possibly hypovolemic shock), airway infections or recurrent pneumonias, urinary tract obstruction owing to herniation of the ureter, chest pain, abdominal pain, vomiting, diarrhea, anorexia, acute abdomen, intrathoracic appendicitis, and other rare presentations.^{160,161}

In bilateral CDH, both sides do not always manifest at the same time. Staggered presentation has been described previously.¹⁶⁵

DIAGNOSIS

The majority of cases are diagnosed before birth, during routine prenatal ultrasound.¹⁶⁶ The relative proportion of cases diagnosed in utero is constantly climbing, because of the increasing application of prenatal ultrasound

screening and improvements in ultrasound technology and resolution. Fetal ultrasonography should always be performed whenever there is polyhydramnios, given that CDH is one of its causes, apparently because of a reduction in the volume of amniotic fluid swallowed by the fetus and probably because of the GI obstruction caused by the hernia. A few authors also recommend careful ultrasonographic examination whenever an amniocentesis shows abnormally low levels of lecithin and sphingomyelin, because of the possibility of an association between CDH and a deficiency in the surfactant system.^{123,124} Such an association, however, has become less accepted.^{126,127,132,133} CDH can be diagnosed with prenatal ultrasound from the eleventh week of gestation until term; previously negative examination results can become positive at any time during pregnancy.^{166,167} False-negative and false-positive examination results can occur; fetal ultrasonography is precise in approximately 90% of cases.^{141,168} Not infrequently, the herniated content identified by prenatal ultrasound can move in and out of the chest, as if the hernia were a dynamic process.¹⁶⁹ A case of CDH diagnosed in the second trimester of pregnancy that seemed to have resolved spontaneously during the third trimester, with delivery of a normal infant, has been reported.¹⁷⁰ There may be inaccuracies as to the side of the hernia, when it is unilateral, and sometimes a bilateral CDH may be diagnosed as unilateral.¹⁶⁹ The differential diagnosis of CDH identified by prenatal ultrasound includes congenital cystic adenomatoid malformation (CCAM) of the lung, diaphragmatic eventration, Morgagni hernia, hiatal hernia, pentalogy of Cantrell, primary diaphragmatic agenesis, pericardial hernia, pulmonary sequestration, lung cysts, diaphragmatic duplication, leiomyosarcoma of the lung, mediastinal teratoma, esophageal atresia with tracheoesophageal fistula, primary pulmonary agenesis, primary pulmonary hypoplasia, and intrathoracic duplications of the GI tract.^{141,171} Color Doppler, three-dimensional ultrasonography, and magnetic resonance imaging (MRI) may all facilitate the prenatal diagnosis of CDH.^{172,173} In the past, in extremely rare, select cases, if in doubt, more invasive exams, such as amniography, computed tomography (CT), or ultrasonography with concomitant intrathoracic or intra-abdominal injection of saline as a "contrast" were considered.^{169,174} But, as fetal MRI has become the new gold standard, these more invasive examinations are of historical interest only. At most referral centers, the prenatal diagnosis of CDH with ultrasound automatically leads to confirmation by fetal MRI, and often an amniocentesis as well, so that the fetal karyotype can be determined. Should certain chromosomal abnormalities be detected, pregnancy termination may be considered.

After birth, a plain chest radiograph is almost always enough to confirm the diagnosis. The typical image is that of bowel loops seen within the lung fields, with deviation of the mediastinum to the contralateral side of the hernia, and decrease or absence of gas in the abdomen (Fig. 33-5). When the radiograph is obtained before the GI tract can be filled with gas, or if the intestines are not herniated (which is more common in right hernias), there may be confusion in the diagnosis. The introduction of a radiopaque gastric tube often helps, in case the stomach

FIGURE 33-5 ■ Typical aspect of plain radiograph from a neonate with a left congenital diaphragmatic hernia. Note the presence of bowel loops in the left hemithorax, the mediastinal deviation to the right, and the gastric tube in the chest.

is herniated (see Fig. 33-5). Should any uncertainty persist, which is uncommon, the diagnosis can be confirmed with a radiograph performed after infusion of contrast through the gastric tube. Even less frequently, an ultrasound may be of help. More rarely, CT, MRI, or a contrast enema can have a role. The differential diagnosis of CDH after birth includes diaphragmatic eventration, pneumonia, CCAM, lung cysts, pneumothorax, pleural collections, Morgagni hernia, hiatal hernia, primary agenesis of the diaphragm, primary pulmonary agenesis, primary pulmonary hypoplasia, pericardial hernia, pulmonary sequestration, cardiac tumors, and duplication of the diaphragm. Despite all these possibilities, the diagnosis of CDH after birth tends to be relatively easy.

On late presentation CDH, the diagnosis is usually made with a simple chest radiograph as well. Also in these cases, a gastric tube may be of help during the interpretation of the radiograph. Sometimes there is previous history of a normal chest radiograph. One must always remember the possibility of late presentation CDH, otherwise the diagnosis will likely be delayed and confused with either pneumonia, pneumatoceles, CCAM, pneumothorax, pleural collections, diaphragmatic eventration, lung cysts, lung nodules, or pulmonary sequestrations. Given that late presentation CDH is relatively rare, the need for other examinations in addition to the chest radiograph is somewhat more common. Such examinations can include an upper GI (often with the patient in Trendelenburg position), ultrasound, CT, MRI, fluoroscopy, and, more rarely, a contrast enema. CDH may be diagnosed as an incidental imaging finding in an asymptomatic patient.

ASSOCIATED ANOMALIES

Children bearing any major congenital anomaly are known to carry a much higher risk of having another anomaly than the general population. Neonates with CDH are no exception to that rule. The incidence of other anomalies associated with CDH in the literature varies from rare to as much as 60%.^{52,54,117,175} There are several different explanations for this disparity: the inclusion, or not, of the other anomalies directly linked to CDH and considered integral components of the so-called CDH syndrome, as described earlier; the inclusion, or not, of stillbirths or patients who die before reaching a referral center; variable diagnostic routines; variable autopsy rates; variable patient populations in terms of the proportion of high risk neonates included in the analysis; and variable regional prevalences of certain congenital anomalies. These studies have identified many different associated anomalies, in all body systems, usually with a predominance of cardiac malformations.

In a detailed review of 166 high-risk neonates (i.e., symptomatic within the first 6 hours of life), we noticed that approximately 40% of the children had one or more congenital anomaly associated with CDH.¹¹⁷ This index was obtained even after exclusion of all the other anomalies that are part of the “CDH syndrome.” Cardiac anomalies were by far the most common, found in 63% of the patients with an associated anomaly, followed by anomalies in the genitourinary tract (23%), GI tract (17%), central nervous system (14%), muscles and skeleton (10%), chromosomes (10%), lungs (5%), and others (5%); in many children there were more than one associated anomaly (Table 33-2).¹¹⁷ Our results were comparable to those from another large series.^{52,175}

The high proportion of cardiac anomalies associated with CDH in many series deserves special attention. In our review, for example, they were more frequent than all other anomalies put together (see Table 33-2).¹¹⁷ Among the cardiac anomalies, heart hypoplasia was the most common.¹¹⁷ This finding is in accordance with many observations pointing to the fact that the cardiac hypoplasia associated with CDH, especially that of the cardiac chambers ipsilateral to the hernia, occurs, like the pulmonary hypoplasia itself, at least in part due to compression of the heart by the herniated content and, perhaps, should also be considered part of the CDH syndrome, as it likely plays a role in the cardiac failure often manifested clinically.^{117,176,177} The presence of an associated cardiac anomaly can lead to significant further reduction of the postductal pO_2 when compared with isolated CDH.¹¹⁷ In fact, in neonates with an excessively low postductal pO_2 , one should be particularly careful in searching for a potential associated cardiac anomaly.

The side of the hernia has been linked to differences in the frequency and pattern of associated malformations.¹⁷⁸ This interesting first observation needs further validation. Patients with late presentation CDH also seem to have a higher prevalence of other anomalies than the general population. However, the related series published thus far are too small for definitive conclusions. For example, in a review of 26 patients spanning 20 years,

TABLE 33-2 Associated Anomalies Identified in 166 High-Risk Patients with Congenital Diaphragmatic Hernia*

Anomaly	Patients (N)	Anomaly	Patients (N)
Cardiac		Absent vermiform appendix	1
Heart hypoplasia	13	Accessory pancreas	1
Atrial septal defect	10	Annular pancreas	1
Ventricular septal defect	9	Duodenal atresia	1
Hypoplasia of aortic isthmus	3	Ectopic liver	1
Aortic coarctation	3	Ectopic pancreas	1
Persistent left superior vena cava	3	Esophageal atresia with transesophageal fistula	1
Ebstein's anomaly	2	Imperforate anus	1
Parachute mitral valve	2	Neuroenteric cyst	1
Abnormal mitral valve	1	Phrygian cap deformity of gallbladder	1
Abnormal tricuspid valve	1	Musculoskeletal	
Absent left pericardium	1	Hemivertebrae	2
Absent right pulmonary artery	1	Absent rib	1
Bicommissural aortic valve	1	Abnormal rib	1
Bifid apex of the heart	1	Accessory rib	1
Common atrioventricular canal	1	Hip dislocation	1
Cor triatriatum	1	Limb dystrophy	1
Double outlet of right ventricle	1	Polydactyly	1
Double coronary ostia	1	Sacral dysgenesis	1
Scimitar syndrome	1	Scoliosis	1
Single coronary artery	1	Chromosomal	
Genitourinary		Trisomy 18	2
Undescended testes	6	Abnormal chromosome 14 centromere	1
Bicornuate uterus	2	Balanced 12/15 translocation	1
Hydronephrosis	2	Chromosome 7Q deletion	1
Horseshoe kidneys	1	Chromosome 12P	1
Hypospadias	1	Mosaic trisomy	1
Renal dysplasia	1	Tetraploidy 21	1
Single kidney	1	Trisomy 13	1
Ureteropelvic junction obstruction	1	Pulmonary	
Vaginal or uterine atresia	1	Pulmonary sequestration	2
Central Nervous System		Pulmonary lymphangiectasia	1
Hydrocephalus	4	Trifurcated trachea	1
Rachischisis	2	Other	
Circle of Willis anomaly	1	Inguinal hernia	2
Microcephaly	1	Omphalocele	2
Myelomeningocele	1	Cleft lip or palate	1
Open spine	1	Conotruncal facies	1
Vascular malformation of cord	1	Torticollis	1
Gastrointestinal			
Meckel diverticulum	6		
Absent gallbladder	1		

*Excluding pulmonary hypoplasia, persistent ductus arteriosus, persistent foramen ovale, intestinal malrotation, gastric volvulus, size abnormalities of the chest wall, accessory spleen or congenital splenic fibrosis in left congenital diaphragmatic hernia (CDH), abnormalities of liver lobulation in right CDH, and hypoplasia or fibrosis of the liver lobe ipsilateral to the hernia.

Berman and colleagues¹⁷⁹ found one or more associated anomalies in 31% of patients.

PROGNOSTIC FACTORS

The search for reliable prognostic markers has been an essential aspect of the study of CDH for decades. Given the broad pathology spectrum related to CDH, such markers are critical for any meaningful comparisons among different therapeutic strategies, and for the identification of cases incompatible with life, in which further efforts would not be justified.

Certain clinical variables are known to be associated with different survival rates. Ever since the study by Young in 1969,¹⁸⁰ there is a well-established reverse relationship between age at the beginning of symptoms and mortality rates.⁵³ Neonates that are symptomatic within the first 6 hours of life are considered high risk, as the lowest survival rates are found in this group of patients.⁵³ There is no difference in mortality between the sexes in isolated CDH; however, higher mortality rates have been reported in females than in males when CDH is associated with other anomalies.⁵² Some studies have shown that the lower the gestational age at birth, or the lower the birth weight, the lower the survival rate.^{53,181} Lower

Apgar scores, particularly in the fifth minute, are also linked to higher mortality.⁵³ Contrary to what a few studies have suggested, the side of the hernia has not had any prognostic effect in the larger series.⁵³ At the same time, the size of the defect is well established as a determining factor not only in survival, but also in the presence of associated anomalies, and in long-term outcome of survivors.^{24,53,182-184} More recently, it has been shown that the presence of a hernia sac also is of prognostic significance, being correlated with better outcomes.¹⁸⁵ The variable with the greatest effect on CDH survival rates is the presence, or not, of other associated congenital anomalies. The prognosis of neonates with associated anomalies, especially cardiac, is overall worse than that of infants with isolated CDH, although it has improved appreciably over time.^{53,117,186,187}

Since the early 1970s, countless studies have tried to correlate mortality to blood gas values or to ventilation parameters, independently, or mutually integrated in often intricate equations. Examples include pH values; best pCO₂ or best pO₂, either postductal or preductal; alveolar-arterial O₂ gradient; mean airway pressure; respiratory rate; pulmonary compliance; dead space; and tidal volume.¹⁸⁸⁻¹⁹³ In the past, perhaps the most popular of these markers was the “best” postductal pO₂ obtained during maximal mechanical ventilation, before either surgically repairing the hernia or placing the patient on ECMO. Children with values greater than 100 mm Hg were labeled *responsive* and had a better prognosis, and vice versa.^{191,192} Other parameters also previously used were the so-called Bohn criteria, which related pCO₂ with the ventilation index (VI = respiratory rate multiplied by mean airway pressure); among the many different combinations, for example, pCO₂ greater than 40 mm Hg with VI ≥ 1000 would suggest high mortality.^{189,191,192} Some authors have proposed that preductal blood gases are more predictive of the degree of pulmonary hypoplasia than postductal blood gases, given that the latter are more influenced by the intensity of pulmonary hypertension and right-to-left shunt; a preductal pO₂ < 100 mm Hg and a preductal pCO₂ > 60 mm Hg would be related to high mortality.^{190,194} As a result of the now universal acceptance of the principle of gentle ventilation, permissive hypercapnia, and minimization of iatrogenic injury related to mechanical ventilation, even preductal blood gases have had increasingly limited prognostic value, at the same time that postductal gases such as best pO₂ during maximal ventilation have been practically abandoned. A recent study from our group has shown that pulmonary support on hospital day 30 is a strong predictor of length of stay, oxygen requirements at discharge, and in-patient mortality, and it can be used as a simple prognostic indicator for family counseling, discharge planning, and a potentially more refined identification of high-risk infants.¹⁹⁵

Imaging criteria as severity predictors have also been extensively studied. One example is the value of prenatal ultrasonography. Until the early 1990s, a positive prenatal ultrasound was considered a marker of bad prognosis, particularly if the hernia was diagnosed before 25 weeks’ gestation.^{196,197} Lately, probably because of the widespread use of fetal ultrasound during routine prenatal

care, the improvements in ultrasound technology, and the novel therapeutic strategies for CDH, it is clear that the prenatal diagnosis of an isolated CDH is, by itself, of no prognostic value, regardless of the gestational age at which it is made.¹⁶⁶ In the event that other associated anomalies, especially cardiac, are diagnosed prenatally in addition to the diaphragmatic hernia, the prognosis is still comparable to that if the diagnosis is made after birth.¹¹⁷ Several specific findings on fetal ultrasound have been proposed as bad prognostic markers, such as polyhydramnios, herniation of the liver and/or the stomach into the chest, “underdevelopment” of the left side of the heart, disproportionate cardiac ventricles, high ratio of the herniated area over the cardiac area, low ratio of the lung area over the total thoracic area, depression or absence of fetal breathing movements, severe mediastinal deviation, reduction of liquid flow through the nose and oropharynx during fetal breathing movements, and disturbances of blood flow modulation through the ductus arteriosus.^{167,196-199} The merit of all these markers, however, is highly controversial and of limited acceptance. The value of liver herniation and the so-called lung-to-head ratio (LHR), which measures the relative proportion between the areas of the lung and the head at predetermined locations, has been emphasized by a few groups.^{200,201} For example, fetuses with liver in the chest and an LHR less than 1 would have a particularly bad prognosis. While there continues to be a debate on the value of the presence, or not, of the liver in the chest, the same cannot be said of the LHR, which at best has been shown to be significantly inconsistent, especially across different institutions.^{159,202,203} Three-dimensional measurements of fetal lung volume with MRI are being increasingly refined and adopted as a seemingly more reliable imaging-based prognostic marker, including at our institution.^{172,204} A so-called CDH congenital composite index, consisting of an amalgam of 10 mainly imaging-based prenatal parameters, has recently been proposed from a single-center study; however, it has yet to be validated by multiple other institutions.²⁰⁵

In like manner, some studies suggest that certain postnatal imaging findings, either independently or in combination, can also be linked to poor outcome. On plain chest radiograph, examples of such findings are the presence of the stomach in the chest, ipsilateral or contralateral pneumothorax, the presence of interstitial emphysema, and a low ratio of aerated ipsilateral lung area over that of the contralateral lung.²⁰⁶⁻²⁰⁸ On an echocardiogram, examples are decreased left ventricular mass, disproportionate dimensions between both pulmonary arteries, and a disproportionately large pulmonary artery trunk in relation to the aorta.^{209,210} Finally, on a pulmonary arteriogram, examples are reduced dimensions of both pulmonary arteries, reduced size of the ipsilateral lung, and severe peripheral compromise.¹⁹¹ Analogous to what happens with prenatal imaging, the predictive value of these proposed postnatal findings is questionable, and few institutions have adopted any of them.

To date, only the following variables have been clearly validated by well-controlled, extensive multicentric data as being of predictive value in CDH: age at the onset of symptoms, birth weight, 5-minute Apgar score, defect

size, and the presence of an associated cardiac anomaly.^{24,53} The meaning of all other suggested prognostic markers is debatable and of limited acceptance. The effect of various prognostic markers seems to differ, depending on the side of the hernia.²¹¹ One of the most common shortcomings of the studies involving prognostic markers is the fact that most of them are reviews from a single institution. Hence, the data are unavoidably linked to the unique patient population and peculiar therapeutic strategies of each service, which are aspects known to still be highly variable from one center to another in CDH. On the other hand, even if well-controlled multicentric trials were conducted, the fact that the treatment of CDH is a constantly evolving moving target could lessen the significance of their results. The introduction of ECMO and of the principle of gentle ventilation are clear examples of the vulnerability of this kind of data, as these therapies rendered the conclusions obtained before their availability nearly useless, even within a given institution. Relatively recently, an empirically weighted mortality prediction score for CDH patients on ECMO has been generated from an extensive retrospective analysis of data from the Extracorporeal Life Support Organization registry, but it has yet to receive widespread acceptance.²¹²

TREATMENT

Except for the rare cases in which there is strangulation of the herniated content, CDH is not a surgical emergency. Rather, CDH is a physiologic emergency. In fact, not infrequently, mechanical aspects of respiration tend to deteriorate after the repair of the hernia.^{213,214} Indeed, emergency surgery is not only unnecessary and often deleterious; a period of preoperative stabilization is known to improve outcome.^{22,215} The child should not go to the operating room while in unstable condition. The time needed for stabilization can vary from less than 12 hours to several days. A few authors even suggest waiting until well beyond stabilization has been reached.²² This recommendation, however, remains somewhat controversial, in that multicentric data have shown good survival even when strict criteria for preoperative stability are not met, suggesting some flexibility in such standards.²¹⁶ At the same time, in certain premature neonates of higher surgical risk, one can wait weeks to a month or longer before proceeding to the repair.¹⁵⁹

The therapeutic strategy in children with CDH and other associated anomalies must be individualized for each patient. The hernia is often repaired before the other anomalies are; however, when CDH is associated with cardiac anomalies, this strategy can lead to unacceptably high mortality.^{117,159} Unless the cardiac defect is mild, the current tendency is to repair the heart before the diaphragm, or, occasionally, both during the same intervention. Yet, the best guidelines for the different scenarios are still being defined.

One of the benefits of the prenatal diagnosis of CDH is the fact that delivery can be planned at a tertiary referral center. The initial results of postnatal resuscitation are known to be maximized when the presence of CDH is detected before birth.¹⁶⁶ At our institution and others,

high-risk outborn infants have a significantly lower survival rate when compared with inborn neonates. Unless there is any obstetrical contraindication, vaginal delivery is preferred over cesarean section.

Preoperative Care

The neonate should be intubated in the delivery room. Ventilation by mask before intubation should be avoided because of the risk for distention of hollow viscera inside the chest. A gastric tube should be introduced and kept under mild continuous suction to minimize such distention and to drain air that might have been swallowed. Central venous access is established, usually through the umbilical vein (occasionally, however, particularly in right-sided CDH, there may be significant distortions of the liver anatomy because of the herniation, which can impede the use of this vein). One of the umbilical arteries is catheterized for blood pressure and postductal blood gas monitoring. Preductal blood gases are obtained through access to the right radial artery, or to one of the superficial temporal arteries. Transcutaneous pulse oximetry monitors and, if available, transcutaneous pO₂ and pCO₂ monitors are placed on preductal and postductal territories. Monitors for body temperature and respiratory rate should also be positioned. At least in the high-risk cases, a Foley catheter is introduced. The volumes of intravenous infusions should be carefully controlled to minimize the chances of a pulmonary edema developing. Prophylactic antibiotics covering both gram-positive and gram-negative bacteria are commonly administered. Whenever possible, inotropic agents should be avoided, given that these drugs usually not only increase cardiac output, but also peripheral vascular resistance, both of which may, together with the ever present pulmonary hypertension, lead to excessive cardiac overload not always tolerated, especially when there is some degree of cardiac hypoplasia.^{117,176} When the use of these drugs is unescapable, many prefer dobutamine, amrinone, or epinephrine to dopamine or norepinephrine, because the former drugs can produce pulmonary vasodilation at low doses.¹⁴¹ One should limit any manipulation or interaction with the infant to a minimum, because of the high volatility of the pulmonary vasculature.

Every neonate with CDH should undergo an echocardiogram with Doppler, given the relatively common occurrence and prognostic effects of both right heart failure and associated cardiac anomalies. Should any functional or structural cardiac disease be identified, its treatment must be carefully coordinated with that of the hernia. A pediatric cardiologist is sometimes a member of the multidisciplinary team caring for these patients. Certain variables, namely prenatal diagnosis before 25 weeks' gestation, low Apgar scores, and "excessive low" postductal pO₂ have shown to be risk factors for the presence of other associated anomalies.¹¹⁷ Should these variables be present, additional examinations such as genitourinary tract and head ultrasounds and a karyotype (if this was not already done during pregnancy) are strongly urged, in addition to the echocardiogram.¹¹⁷

Until the early 1990s, typically neonates were sedated, paralyzed, and hyperventilated, and they received

systemic alkalization with sodium bicarbonate or throtamine to minimize pulmonary hypertension. Ventilation parameters used to be controlled by postductal blood gases. This strategy, which unfortunately is still practiced by many centers today, is clearly associated with unacceptably high risks for iatrogenic lung injury. Pulmonary hypoplasia and, in particular, pulmonary hypertension are both expected to lead to low pO_2 and high pCO_2 , especially in postductal gases. Attempts to normalize postductal blood gas values often lead to marked increases in ventilator parameters, namely respiratory rate (RR), inspired O_2 fraction (FiO_2), peak inspiratory pressure (PIP), positive end-expiratory pressure (PEEP), and mean airway pressure (MAP), which, in turn, commonly lead to hyperdistention of the lungs and severe barotrauma, not to mention the toxicity of high FiO_2 levels. A survey involving clinical and autopsy data for 68 children with CDH treated in this fashion showed a tremendously high frequency and severity of iatrogenic insult to the pulmonary parenchyma.¹⁷⁷ In that study, 91% of the patients had evidence of diffuse alveolar damage with development of hyaline membrane, more obvious in the ipsilateral lung. Moreover, 65% of the children developed pneumothorax, 51% had pulmonary hemorrhage, and 6% already had variable degrees of interstitial fibrosis.¹⁷⁷ Other studies also showed alveolar ruptures, damage to the alveolar basal membrane, alveolar hemorrhage, and edema, all of which contributed to atelectasis, a decline in lung compliance, and even further deterioration of gas exchange.^{16,127} In addition to barotrauma, to which CDH neonates are particularly vulnerable,¹³⁶ pulmonary hyperdistention leads to even further increase of the already elevated pulmonary vascular resistance, thus worsening the effects associated with pulmonary hypertension.^{217,218} Systemic alkalization with sodium bicarbonate can lead to increases in pCO_2 and to volume and sodium overloads. Throtamine can be useful at times in the short term, but relatively large volumes of this drug are usually necessary, which tends to result in both generalized and pulmonary edema.

It is clear that a completely different strategy, first proposed by Wung and colleagues,^{21,22} should be offered to high-risk neonates with CDH. It is based on the following guidelines: minimal sedation; no muscle paralysis; respiration merely assisted by the mechanical ventilator, if possible through pressure support under flow synchronization, or, if this is not available, then through simple or synchronized intermittent mandatory volume; permissive hypercapnia with no hyperventilation; and no systemic alkalization. Patient monitoring is mostly through preductal gases. Ventilator parameters are left at a minimum necessary to maintain preductal O_2 saturation (SaO_2) greater than or equal to 90%, whichever the postductal values may be, with tolerance to high pCO_2 levels. In general, the ventilator parameters are left at: base RR ≤ 40 breaths per minute, PIP and PEEP no greater than 30 and 5 cm H_2O , respectively, and the FiO_2 should be the lowest possible to prevent severe preductal hypoxemia. That is to say, unless there is metabolic acidosis, suggesting excessively low O_2 delivery, one should tolerate low postductal pO_2 and SaO_2 , as long as there is an adequate amount of oxygen in the preductal blood that is going to the brain

and to the heart. As long as the pH is at "acceptable" levels, one should tolerate hypercapnia. The main goal of this therapeutic strategy is the prevention of barotrauma, probably the most common cause of death whenever the old "conventional" hyperventilation strategy is used.^{16,22,194,219} Despite the known benefits of sedation in CDH, which raises the excitability threshold of the pulmonary vasculature, in this "new" strategy, one must use sedation with great caution, so that the child may be able to effectively activate the mechanical ventilator, preferably in pressure support under flow synchronization. When the child is able to control both the RR and the air flow from the respirator, he or she can contribute more to the minute volume without compromising the functional residual capacity. This therapeutic strategy also avoids the side effects of systemic alkalization.

As discussed, the lungs of newborns with CDH are particularly vulnerable to barotrauma, so the occurrence of pneumothorax is relatively common. Except for rare occasions, one should not drain a pneumothorax ipsilateral to the hernia before surgical repair, given the risk of iatrogenic injury to the herniated content.

Pulmonary Vasodilators

Regardless of the ventilation strategy, many vasodilators administered systemically have been used in an attempt to control the pulmonary hypertension. Examples of these agents are: tolazoline, nitroglycerin, nitroprusside, acetylcholine, prostaglandin E1, prostaglandin D2, prostacyclin, isoprenaline, and nifedipine. Despite the theoretical appeal of these drugs, they are not selective enough to the pulmonary vasculature, and they usually lead to a drop in both total peripheral vascular resistance and systemic arterial pressure. Therefore, their effects on the pressure gradient through the ductus arteriosus is either minimal or inexistent, so that the tendency to right-to-left shunt is unchanged. Furthermore, they can lead to vasodilation of poorly ventilated areas of the lungs, which can worsen the intrapulmonary right-to-left shunt. The drop in systemic arterial pressure, on the other hand, can lead to the administration of volume or inotropic agents, both of which should be avoided. Bos and colleagues²²⁰ reported a reduction of both the alveolar-arterial O_2 gradient and the oxygenation index ($OI = MAP \times FiO_2 / pO_2$) after administration of prostacyclin in high-risk CDH patients, but this had no effect on survival. The use of prostacyclin is also associated with an increase of the bleeding time, which is obviously undesirable in surgical patients.^{220,221} Inhaled prostacyclin has been investigated experimentally, but no clinical applicability has been found.^{222,223} The response to prostaglandin D2 is variable, and systemic hypotension is a common side effect.^{140,220,223} The most popular of these vasodilators was, perhaps, tolazoline, an α -adrenergic receptor blocking agent with a mild inotropic and chronotropic effect on the myocardium. This drug also lowers the levels of thromboxane B2, which is possibly a mediator of pulmonary hypertension in CDH and which also has histamine-like effects.^{141,224} Children who respond to tolazoline usually do so within 4 hours after an initial bolus of 1 to 2 mg/kg, which may be noticed by an increase in the postductal

pO₂. This bolus is commonly followed by a continuous infusion of 1 mg/kg per hour. The infusion of vasodilators directly into the pulmonary artery has been shown not to have any advantage over their systemic or peripheral administration.²²⁵ Tolazoline side effects can be severe and include systemic arterial hypotension, upper GI hemorrhage, thrombocytopenia, hyponatremia, and skin rubor.^{141,224} In case there is upper GI hemorrhage, one should give priority to antacids and gastric lavage, given that tolazoline may inhibit the effects of cimetidine.²²⁶ Tolazoline, as well as these other vasodilators, can occasionally contribute to the stabilization of the patient, sometimes lengthening the honeymoon period. However, this is not often the case and, even when there is some improvement in oxygenation, no beneficial effect on survival has been demonstrated.^{22,215,220} Indeed, most referral centers no longer use systemically administered pulmonary vasodilators.

Sildenafil has been proposed as beneficial in the management of pulmonary hypertension associated with CDH.²²⁷⁻²²⁹ The initial reports were arguably encouraging, but its therapeutic value remains to be defined.

Nitric Oxide

The most potent selective pulmonary vasodilator known is nitric oxide (NO) administered by the endotracheal route. NO is a natural mediator of smooth muscle relaxation in general, but acts only locally because of its extremely short half-life. It is responsible for the biological activity of the so-called endothelial-derived relaxing factor.²³⁰ When given as part of the inspired air, NO crosses the alveolar-capillary membrane by diffusion and stimulates the cyclic guanosine 3',5'-monophosphate (cyclic GMP) in the smooth muscle of the pulmonary arterioles, inducing vasodilation. Its effects are limited to the pulmonary vasculature because it quickly combines with hemoglobin and is deactivated.

At first, there was great enthusiasm in relation to the use of NO for the treatment of CDH; however, clinical experience has been disappointing. Occasionally, NO does help in stabilizing the patient; however, even when there is an initially satisfactory response, there may be tachyphylaxis and, to date, improvements in outcome related to its use remain to be demonstrated.^{159,231,232} In fact, studies involving term neonates with respiratory failure of different causes have shown that inhaled NO improves oxygenation and lowers the need for ECMO in all diagnosis, except in CDH.²³³ The underlying reason why CDH neonates are often unresponsive to NO remains unknown. There has been some evidence that, if combined with the administration of surfactant or with liquid ventilation, NO can improve oxygenation and lower the pulmonary vascular resistance of children with CDH.^{127,234} At most referral centers, the role of NO in CDH remains confined to the management of right cardiac failure, when present.

Surfactant

Given the possibility of a deficiency in the surfactant system in children with CDH, endotracheal instillation

of exogenous surfactant has been studied as a therapeutic adjunct for many years. The results obtained thus far, however, do not justify its widespread application—that is, other than when prematurity itself is the indication for its use.^{132,133}

Prenatal administration of corticosteroids is known to induce, or at least increase, the production of endogenous surfactant.²³⁵ Although the precise mechanisms behind this phenomenon have yet to be elucidated, studies exploring this response in the treatment of CDH have been proposed.²³⁵

Alternative Forms of Mechanical Ventilation

Alternative forms of mechanical ventilation have also been used in CDH. One example is high-frequency oscillatory ventilation (HFOV), which mobilizes volumes smaller than the anatomic dead space, at frequencies of up to 40 Hz. Gas exchange seems to occur not from the delivery of gas under positive pressure, as in conventional mechanical ventilation, but through a diffusion process. Compared with conventional ventilation, it is thought that HFOV minimizes barotrauma and facilitates gas exchange, especially CO₂ elimination, in select circumstances. This form of ventilation, either isolated or combined with NO, has been tested in many institutions for the support of CDH patients, usually with less than satisfactory results.^{159,236} Similar to NO, HFOV seems to be an option only in select cases, yet to be better defined. When analyzed as a whole, the experience with HFOV in CDH has been disappointing.¹²⁷ However, Bohn has proposed that, as long as HFOV is not used for lung recruitment, but with mean airway pressures no higher than 14 to 16 cm H₂O and peak-to-peak airway pressures limited to 35 to 45 cm H₂O, it can lead to improved survival, especially if used early, rather than in a rescue mode.²³⁷ Other authors have also advocated the value of HFOV in CDH, within specific guidelines.¹⁸⁶

Intratracheal pulmonary ventilation, a form of ventilation that promotes active expiration, drastically lowering dead space and thus enhancing CO₂ elimination and minimizing barotrauma, has been used in a handful of CDH cases, with promising preliminary results.²³⁸ Regrettably, broader, definitive studies have been stalled by regulatory constraints and conflicting patent interests.

Liquid ventilation with a perfluorocarbon (PFC) has also been examined for some time. PFCs are bioinert, nonabsorbable by the alveolar-capillary membrane, and may carry large amounts of both O₂ (in particular) and CO₂. Besides, they display low surface tension levels, thus acting as truly artificial surfactants. Hybrid liquid ventilation (i.e., with a PFC and a gas) is known to increase pulmonary compliance and to improve gas exchange, especially oxygenation.²³⁹ The improved oxygenation, in turn, optimizes redistribution of pulmonary blood flow, hence alleviating the pulmonary hypertension.²³⁹ Liquid ventilation, either isolated or in combination with NO, has been applied in a few CDH cases, with encouraging results.^{239,240} However, its effect on outcome and role in the treatment of CDH, if any, is yet to be established.^{127,241}

Extracorporeal Membrane Oxygenation

Since the mid-1980s, extracorporeal life support has left the realm of experimental therapy and has become part of the standard therapeutic options in CDH. Several early studies showed that the introduction of ECMO resulted in a significant increase in survival of these patients.^{16,215,242-244} The significance of these studies, however, was limited by the relatively small number of patients and by the fact that each involved a single institution. A multicentric review by the Congenital Diaphragmatic Hernia Registry, involving 632 patients from 65 centers, showed that ECMO improved survival from 53% to 77% in children with high mortality markers and comparable prognosis.¹²⁷ That same study also showed a direct relationship between the severity of the cases and the beneficial impact of ECMO on outcome.

During extracorporeal support, there is not enough time for the lungs to grow to the point of reversing the pulmonary hypoplasia. However, ECMO acts as a bridge, lessening if not eliminating the component of pulmonary vascular hyperreactivity, allowing for maximum pulmonary remodeling, with an increase in compliance of the pulmonary arteries and arterioles, which normally takes place after birth,^{115,130} as well as reducing barotrauma to a minimum. There is still some debate regarding the best moment to administer ECMO in relation to the time of surgical repair of the hernia.¹⁷ There were no differences in survival when preoperative versus postoperative commencement of ECMO was compared.^{245,246} The current trend at most referral centers, however, is to use ECMO during preoperative stabilization, with repair of the hernia done either after ECMO decannulation, or while still under bypass.^{16,247,248} Despite the need for anticoagulation during ECMO, it has been shown that certain pharmacologic precautions and technical principles allow for safe surgical intervention during bypass, with a minimum risk of hemorrhagic complications.^{16,248-250} Occasionally, a patient may be in stable condition without the need for ECMO in the preoperative period, deteriorating either during or soon after the operation, and needs to then undergo bypass.

A few authors have proposed criteria for the contraindication of both ECMO and surgical repair, which would supposedly be linked to pulmonary disease incompatible with life.^{22,114,190,194,215} Given the many reports by other groups showing survival of patients who had met such criteria,^{16,243,245,251} not to mention the controversies related to the prognostic markers of CDH in general, we offer ECMO and surgery to virtually every patient, unless the presence of other associated anomalies is deemed incompatible with life.

The specific criteria for placing a patient on ECMO are equally debatable. Given the many controversies surrounding prognostic markers in CDH, it is no surprise that the many proposed indications for ECMO in this disease have not been widely accepted. Usually, the indications for ECMO in other diseases do not apply to CDH, mainly because the mechanical ventilation parameters used in other diagnosis before considering ECMO would be unacceptably toxic to the lungs of children with CDH, which are particularly vulnerable to iatrogenic

injury. In most centers, ECMO is considered when the patient with CDH cannot be adequately maintained without the use of toxic ventilator parameters. The definition of such toxic parameters is highly variable from one institution to another. As mentioned previously, in general we do not allow for the PIP and PEEP to be higher than 30 and 5 cm H₂O, respectively; it should be possible to gradually lower the FiO₂ to 60% or less in no more than 72 hours, and the base RR on the ventilator should not exceed 40 breaths/min, although a much higher RR from the child is tolerated, when he or she is under flow synchronization on the ventilator. The ventilation parameters are controlled mostly by preductal blood gases. In case the patient cannot be maintained under these guidelines, the use of HFOV and/or NO may be considered in select cases. However, extracorporeal bypass is usually indicated immediately. A potential benefit of placing infants with severe pulmonary hypoplasia on bypass already in the delivery room, the so-called *ex utero* intrapartum (EXIT)-to-ECMO procedure has been evaluated at select referral centers more recently. Our own experience with EXIT-to-ECMO in neonates with less than 15% predicted lung volume does not support an indication for this procedure, at this time.²⁵² Whenever possible, venovenous ECMO is preferred over the venoarterial mode.^{16,246} In case ECMO is initiated preoperatively, we perform the repair on bypass; however there are no data to indicate that the timing of surgery has any effect on survival.

Surgery

If the patient is on ECMO, we begin a continuous infusion of aminocaproic acid (AMICAR), an inhibitor of fibrinolysis, approximately 2 hours before the operation, concomitantly with reductions of the activated clotting time (ACT).^{248,250} If the patient is on HFOV and/or NO administration, they need not be discontinued during the procedure; they can be useful in select cases. If ECMO, HFOV, or NO are not being used, the best form of intraoperative ventilation is one at low pressures and high respiratory rates, with a dedicated infant or pediatric ventilator. Conventional anesthesia ventilators are excessively compliant and have too much dead space, and they are not suitable for these children.

In addition to general inhaled anesthesia, we recommend the routine introduction of a catheter for continuous epidural anesthesia, which allows for early withdrawal of curare in the postoperative period, as well as for maintenance of abdominal wall relaxation.¹⁶ All these effects, in turn, facilitate early postoperative resumption of flow synchronization and minimize volume retention, commonly associated with the continued use of curare. NO should not be used, because it tends to cause bowel distention, which can hinder hernia reduction and abdominal closure.

The patient is positioned supine and slightly tilted to the side contralateral to the hernia by a small support placed under the ipsilateral thoracoabdominal transition. An abdominal access is preferred over a thoracic one, usually through a subcostal laparotomy.¹⁷ After careful reduction of the herniated content, one should always

inspect the ipsilateral lung. Should it not be visible, the presence of a hernia sac, which is not always easily identifiable, must be investigated. If present, the hernia sac should be separated from the diaphragm and at least partially resected. Frequently, it is necessary to detach the posterior aspect of the residual diaphragm from the posterior abdominal wall, after opening the peritoneum and the pleura, which usually cover that area.

Whenever possible, a primary repair of the hernia is performed, with nonabsorbable sutures (Fig. 33-6). Yet, one should not force a primary repair under tension, because of the following potentially harmful consequences: the diaphragm will become flat and tense, minimizing, if not eliminating its functionality; there will be an excessive enlargement of the thoracic cavity, which may lead to alveolar hyperextension in the ipsilateral lung and consequent worsening of the pulmonary hypertension and barotrauma; the tension exerted on the diaphragm may be transmitted to the rib cage, resulting in chest wall deformities; and, finally, there will be further decrease of the abdominal cavity volume, hampering closure of the laparotomy.²⁵³ According to the Congenital Diaphragmatic Hernia Registry, approximately half of the patients receive a “patch” of some kind to have the diaphragm closed.^{17,35} In case a tension-free primary repair is not possible, several alternative techniques have been proposed, including abdominal or thoracic muscle flaps, free fascia lata grafts, and a myriad of prostheses, such as lyophilized dura mater, silicone, Dacron, polypropylene (Marlex, C. R. Bard, Inc., Murray Hill, NJ), polytetrafluoroethylene (PTFE, or Teflon; DuPont, Wilmington, DE), composite prosthesis, and others.^{17,215,254-260} Regardless of the technique used, care should be taken not to leave the diaphragm too flat, but with a slight to moderately sized dome, so that the same problems associated with primary closure under tension can be avoided.²⁵³ The dome should not be too pronounced, otherwise local paradoxical respiration can ensue. We and many others do not favor muscle flaps because of the residual defects left in the abdominal or thoracic walls, as well as the increased risk for local hemorrhage, particularly if ECMO is or may be used; however, this form of repair does have a sizeable following. At most

FIGURE 33-6 ■ Primary repair of a diaphragmatic defect in a newborn with congenital diaphragmatic hernia.

U.S. centers, pediatric surgeons favor the use of either a prosthesis made of expanded Teflon (Fig. 33-7) or a Teflon–Marlex composite. At least part of the reasons for such a preference for Teflon derive from a study showing improved incorporation by the host and a better motility pattern of this prosthesis in the short term, when compared with silicone prosthesis and muscle flaps.²⁶¹ A number of acellular biological prostheses, including acellular human dermis, cross-linked porcine dermal collagen, and porcine small intestinal submucosa, have also been studied experimentally, with conflicting results.²⁶²⁻²⁶⁶ Among these results, small intestinal submucosa and acellular human dermis have mostly led to disappointing results, whereas cross-linked porcine dermal collagen (Permacol) may hold some promise, albeit yet to be confirmed by more than one center.²⁶⁶ When the posterior residual diaphragm is not large enough for proper suturing, one option is to pass the suture around the subjacent rib, after gentle anterior traction of the rib with a clamp, to avoid injury to its neurovascular bundle.

Soon before completion of the diaphragmatic closure, a multiperforated tube is placed into the pleural cavity, exteriorized through the chest, and typically just placed under water seal. Continuous suction through the chest is usually avoided, because of the possibility of pulmonary overdistention, which is highly detrimental in CDH. Many authors even recommend that a chest tube not be placed at all.^{22,267} In a review by the Congenital Diaphragmatic Hernia Registry, 24% of the patients did not receive a chest tube.¹⁷

We prefer to correct the intestinal malrotation, almost always present; however, most centers do not perform this maneuver.¹⁷ In most institutions, including ours, an appendectomy is not routinely done, in order to minimize morbidity.¹⁷ Given the reduced abdominal volume, difficulty closing the abdominal wall is not uncommon. Should there be excessive intra-abdominal tension after abdominal wall closure, a syndrome of compression of the inferior vena cava may develop, along with a decrease in thoracic expansibility and tidal volume. To prevent

FIGURE 33-7 ■ Prosthetic repair of a diaphragmatic defect with expanded Teflon (DuPont, Wilmington, DE) in a newborn with congenital diaphragmatic hernia.

this, repeated digital distention of the abdominal wall and evacuation of intestinal gas may be of help. Some have suggested a routine gastrotomy as an additional means to decompress the stomach, facilitate abdominal closure, and minimize postoperative respiratory complications, but there has been no evidence-based support for this idea.^{247,268} When tension-free closure of the abdominal wall is not possible, the use of an abdominal silo should be considered, followed by postoperative serial reductions and definitive primary closure.^{22,215,269} Another option is simply to close the skin, leaving the proper, definitive closure for a later date.²⁴⁸ The need for either of these maneuvers, however, should be extremely rare.

In children on ECMO, a few technical precautions should be taken to prevent excessive bleeding: the skin should be open with needle-tip electrocautery; when primary diaphragmatic closure is unlikely, one should not dissect the posterior residual diaphragm, if it is adhered to the posterior abdominal wall, but pass the stitches around the subjacent rib, as described above; finally, fibrin glue should be applied to the diaphragmatic suture line and other raw surfaces.²⁴⁸ We do not leave a drain in the abdomen. If the abdominal wall cannot be closed primarily and a silo is implanted, serial reductions should commence only after the child comes off bypass.

Thoracoscopic and laparoscopic repairs of CDH have been used increasingly.²⁷⁰⁻²⁷² During thoracoscopy, reduction of the hernia can even be facilitated by the mild positive intrathoracic pressure often applied intraoperatively. These procedures have also proved viable in the presence of associated cardiac anomalies, as well as for the placement of prosthetic patches. On the other hand, a recent randomized controlled trial has shown that thoracoscopic repair of CDH is associated with prolonged and severe intraoperative hypercapnia and acidosis, compared with open surgery, calling into question the safety of thoracoscopy with CO₂ insufflation and conventional ventilation for the repair of CDH.²⁷³ That study was preceded by another one from the same group showing decreased cerebral oxygen saturation during thoracoscopic repair of CDH.²⁷⁴ The precise indications, pros and cons of the so-called minimally invasive repair of CDH are yet to be fully clarified. A possible beneficial role for intratracheal pulmonary ventilation during the procedure in severe cases has been proposed in an animal model.²⁷⁵

Postoperative Care

If the patient was not on ECMO during surgery, mild ventilatory support under flow synchronization, as described above, should resume as soon as possible, if necessary with pharmacologic reversal of the muscle paralysis, in case it had to be used. This transition can be tremendously facilitated if the child was placed under continuous epidural anesthesia intraoperatively.¹⁶ The principles guiding mechanical ventilation described for the preoperative period also apply to the postoperative period. The same is true for the criteria to go on ECMO.

Although some children improve after repair of the hernia, frequently there is (at least temporary) deterioration of the respiratory mechanics in the immediate

postoperative period.^{213,276} This phenomenon is thought to be due to anatomic distortions on the diaphragm and thoracic cavity, to hyperinflation of both lungs, and to an increase of the intra-abdominal pressure.²⁷⁶ Under these circumstances, the ventilator parameters may need to be temporarily "increased," sometimes to the point that alternative modes of ventilation and even ECMO may have to be used. Occasionally, children that had been on bypass preoperatively and were decannulated before the operation may need to go back on ECMO (this also is one of the reasons why we prefer to perform the repair on bypass).

Another potential complicating factor is the administration of intravenous fluids, which must be controlled carefully. Concomitantly to the common risk of hypovolemia, related to surgical trauma and bleeding, neonates with CDH, more so than newborns with other surgical diseases, initially behave as if with inappropriate secretion of antidiuretic hormone and may tend to retain excessive amounts of water.²⁶⁹ The explanation for this phenomenon is not yet clear. This predisposition must be recognized early, otherwise patients can be overloaded with fluids, with harmful consequences to their respiratory and cardiac status.

Sometimes, intra-abdominal pressure rises significantly in the immediate postoperative period. One should be attentive to signs of inferior vena cava syndrome, which can lead to a decrease in the venous return to the heart, impairment of renal blood flow, or a reduction in tidal volume. Should there be any evidence of renal insufficiency or major worsening of the respiratory or cardiac status, one must consider muscle paralysis, which may lower the intra-abdominal pressure. In the more severe cases, it may be necessary to take the child back to the operating room for placement of an abdominal silo.

Whenever the chest tube is used, it is not continuously aspirated, but only placed under a passive water seal to avoid pulmonary hyperdistention, which can occur on both lungs because of the large empty residual space within the ipsilateral pleural cavity.^{22,276} The chest tube should be removed only after the patient is extubated, usually after liquid drainage ceases. Not infrequently, liquid drainage lasts for a long period of time, until the lung can occupy the whole pleural space. In these circumstances, one may consider removing the chest tube while it is still draining fluid and tolerate a temporary pleural collection.

Children on ECMO should continue to receive AMICAR, in parallel to the maintenance of ACT levels lower than usual for bypass.²⁴⁸ When AMICAR is not used, or the technical precautions described above are not duly followed, the incidence and severity of hemorrhagic complications tend to be high.^{215,277} Should there be bleeding, surgical dressings must be regularly weighed and the losses through the chest tube and abdominal drain (if present) must be quantified. In our service, blood losses equal to or higher than 20% of a patient's total blood content in 8 hours or less, or progressive abdominal distention, is a criterion for surgical re-exploration. Frequently, one cannot find specific areas of bleeding during reoperation, but a diffuse oozing throughout the operative field. In these cases, more aggressive

pharmacologic management related to AMICAR and ACT levels must be pondered. In addition to these potential surgical complications related to ECMO, the common risks associated with extracorporeal bypass itself are, obviously, also a possibility.

More rarely, GI obstruction resulting from adhesions, gastric volvulus, or midgut volvulus can occur even in the immediate postoperative period.²⁷⁸ Other rare complications are chylothorax and chylous ascites.²⁷⁹⁻²⁸¹ In the few cases reported to date, the causes for these chylous collections have not been clearly determined. Their treatment should be based on parenteral nutrition, feedings with middle chain triglycerides and, if necessary, occasional needle drainages.²⁷⁹⁻²⁸¹

Late-Presentation Congenital Diaphragmatic Hernia

Regardless of its initial clinical presentation, including cases of purely incidental findings, late-presentation CDH should be repaired as soon as possible because of the risks of incarceration and strangulation of the herniated content, and even sudden death.²⁸²⁻²⁸⁴ In these cases, a laparotomy is still the preferred access; however, a thoracotomy can be considered much more frequently than in neonates whenever the presence of firm adhesions within the herniated content into the chest is suspected. Frequently, one cannot determine preoperatively whether a laparotomy or a thoracotomy would be the best access and personal, somewhat subjective preferences may play a role in the decision process. Minimally invasive access can be justified in select cases.

RESULTS

Even at referral centers with all known therapeutic options for treatment of CDH available, there may be a sizeable variability of the survival rates associated with this disease. These differences are due to several reasons. On one hand, patient population profiles can vary in regard to the proportion of high-risk neonates from one institution to another. In addition, patients may die before reaching a center and thus not be included in the final numbers; it is the so-called hidden mortality originally described by Harrison and colleagues.²⁸⁵ At the same time, a few authors deliberately exclude children considered to have pulmonary hypoplasia incompatible with life, often based on arguable criteria, which artificially improve survival rates.^{190,194} The same is true for the inclusion, or not, of children bearing other congenital anomalies associated with CDH.^{117,187} In addition, there are still major differences among institutions related to therapeutic protocols/strategies. Such heterogeneities, combined with the different sizes of the review series and the constant evolution of the treatment options for CDH, can limit one's interpretation of the results.

Bearing in mind the limitations described above, the latest meaningful reviews have shown that overall survival for isolated CDH at many referral centers has been close to 80%, a sharp increase from the depressing figures of a little over 20 years ago, when ECMO was not widely

available and aggressive hyperventilation was still the norm.^{24,35,127,194} At our institution, more than 80% of the diagnoses are prenatal. As a consequence, their delivery can be planned, usually at one of two sister institutions linked to our hospital. The few cases diagnosed only after birth within our referral base are rapidly transferred to us, consequently our "hidden mortality" is practically zero and our patient population is large and illustrative. In accordance with the data from other referral centers, our survival rates for high risk neonates ($\approx 90\%$ of our cases) had varied between approximately 85% and 90% for isolated CDH and had been approximately 70% when all cases, including those with other associated anomalies, were considered.^{16,127,286} These numbers were intimately related to the application of the principle of gentle ventilation and permissive hypercapnia, as well to the liberal and early indication for ECMO. In the past several years, our overall survival has surpassed 80%, by adding careful attention to the right heart to the management principles outlined earlier.²⁸⁷ Among the several other anomalies that can be associated with CDH, the most common of them, cardiac defects, deserve special consideration as to their effect on outcome. Not long ago, cardiac anomalies were a virtual harbinger of a death; now they are associated with a highly variable overall prognosis, regardless of type.¹⁸⁷ In non-high-risk patients (i.e., when an isolated CDH becomes symptomatic after 6 hours of life), survival is close to 100%.^{127,194}

LONG-TERM FOLLOW-UP

At the same time that CDH survival rates have almost skyrocketed lately, perhaps predictably so, morbidity rates have worsened. High-risk children who would otherwise have died not long ago, now survive often with multiple problems, in various systems, and they need to be followed by a dedicated, multidisciplinary team.^{281,286,288-291} Although this seems to be somewhat more evident in patients who had to go on ECMO, it is currently a universal trend, which also applies to those who did not need bypass.^{281,286,290,291} In many series, including ours, there is a direct relationship between the need for prosthetic diaphragmatic repair and the incidence and severity of late complications.^{286,288,290,291}

One of the most common problems in CDH survivors is gastroesophageal reflux (GER).^{*} In our experience, virtually every child has some manifestation of GER, but only approximately 20% of them need to undergo a fundoplication.²⁹¹ It has been suggested that, in addition to GER, esophageal motility is often abnormal, not infrequently with concurrent esophageal dilation, hindering management of the GER itself.²⁹² In addition to the expected and well-documented adverse effects of CDH in esophageal topography and in the angle of His, at least in experimental CDH, abnormalities in intrinsic esophageal innervation have also been demonstrated, which may correspond to an unrecognized equivalent in humans, possibly contributing to this common clinical scenario.²⁹³

*References 215, 247, 281, 286, 288, 289, 291, 292.

In comparable manner, deficient enteric innervation and impaired gastrointestinal motility have been described in the nitrofen model of CDH, the clinical significance of which remains to be determined.²⁹⁴ In our series, more than half of the children stayed below the 25th percentile for weight during the first year of life, despite a higher than normal caloric intake.²⁹¹ Up to two thirds of the children may need a gastric tube or gastrostomy to be fed adequately, usually because of oral feeding difficulties.^{281,288,292} Prolonged endotracheal intubation is predictive for severe oral aversion, which was found in one quarter of our patients during the first year of life.²⁹¹ Most of these gastrointestinal and nutritional complications tend to improve with age.²⁹¹

Bronchopulmonary dysplasia, or “chronic lung disease,” is present in one to two thirds of patients.^{288,295} The need for continuous oxygen delivery through a nasal catheter after hospital discharge is not uncommon (16% of the cases, in our experience), in some patients for more than 2 years.^{159,281,288,290} Volume restrictions, usually through diet based on hyperosmolar formula, may help minimize pulmonary complications.²⁸¹ Diuretics, sometimes in association with bronchodilators or steroids, may also be useful.^{288,290} In our patients, prophylaxis against respiratory syncytial virus has been proposed as a means to decrease both the incidence and severity of acute respiratory failure related to this disease.²⁹⁰

Although the alveoli continue to multiply during the first 8 years of life,^{120,296} their total numbers do not reach normal values in CDH.^{113,115,116,297} Emphysematous changes may occasionally be seen on plain chest radiographs, especially in the more caudal portions of the lungs.²⁹⁸ Radioisotopic pulmonary scans usually show reductions on both ventilation and perfusion, which are also typically disproportionate to each other.^{290,298} Interestingly, despite all these initial disturbances, pulmonary function seems to normalize in the long term.^{134,299,300} Pulmonary artery pressure, estimated by Doppler echocardiogram, tends to normalize with time in most children. However, deaths from right cardiac failure have been reported as late as 18 months of age.²¹⁵

Different factors, including hypoxemia, ventilation strategy, and ECMO, can affect the neurodevelopmental outcome. Furthermore, fetal cerebral blood flow velocities have been shown to be decreased in fetuses with CDH, although overall cranial and cerebral growths tend not to be conserved.³⁰¹ In general, the overall incidence of neurologic complications in patients that received ECMO for CDH is comparable to that found in infants who required bypass because of other diseases.^{302,303} There is some controversy, however, regarding purely cognitive development. Although a few authors have found cognition problems to be more frequent in CDH children than in those who went on ECMO for other reasons, others have not confirmed such findings.^{286,302,303} In most cases, such impairment is mild or moderate.^{281,286,288,302,303} Children with continued need for oxygen therapy and/or failure to thrive seem more susceptible to neurodevelopmental complications.³⁰⁴ Otherwise, neurodevelopmental delays tend to disappear, or at least improve with age, with patients typically functioning within the average range as early as preschool ages.^{281,286,304}

Hearing deficits and need for hearing aids have been noticed in up to one fifth of the children, for reasons yet to be completely clarified.^{281,286,288,289} Putative causes include prolonged alkalosis, the use of aminoglycoside antibiotics, and the administration of high doses of furosemide.²⁸¹ ECMO is also a risk factor.³⁰⁵ Every child with CDH, particularly those with speech delays, must undergo screening audiometry and brain-stem auditory evoked response testing periodically, given that hearing deficits may have a delayed onset.^{281,286}

Chest wall development can be affected by the disease itself and its treatment. The volume of the ipsilateral thoracic cavity may be reduced, apparently as a consequence of the reduced size of the lungs.³⁰⁶ Overall, up to one third of the children have some degree of chest wall deformity, more commonly pectus excavatum and thoracic scoliosis; the latter is a risk factor for hernia recurrence in children who receive a diaphragmatic prosthesis.^{281,286} In general, chest wall deformities associated with CDH are mild and rarely need surgical repair.^{281,286}

Several other complications have been reported in different systems. Intestinal obstruction is the most frequent reason for reoperation in our experience, occurring in less than 20% of cases.²⁸¹ Its most common causes are adhesions, followed by midgut volvulus and gastric volvulus.^{281,286,288} A number of other ailments have also been reported in association with CDH, albeit much less frequently, including vesicoureteral reflux, cholelithiasis, asymptomatic renal calculi, chylothorax, hypertrophic pyloric stenosis, retinal vasculopathy without functional visual deficit, and chronic superior vena cava syndrome (the latter two complications were likely related to ECMO).^{281,286,288}

Diaphragmatic Hernia Recurrence

Overall postoperative recurrence rates have been reported to be between 6% and 80%.[†] Recurrence rates constitute a moving target, given the not uncommon introduction of new materials and/or techniques over time. Hernia recurrence is more common within the first 18 months of age, but it can happen at any age.³⁰⁷ The vast majority of the cases occur in children in whom a prosthetic patch was used for repair of the hernia, with approximately half of them progressing with a recurrence in the larger and longer series.^{247,281,302,307} Diaphragmatic repair with a prosthesis has also been associated with higher rates of infection, adhesions, and both thoracic and spinal column deformities, when compared with primary repair.^{288,309,310} There are conflicting data as to whether split abdominal wall flap repairs are associated with higher rates of recurrence than that of prosthetic patches, or not.^{308,311,312} Either way, these types of repair also fail more often than primary repairs and of course leave a residual abdominal defect. It remains unclear whether minimally invasive approaches have an effect on recurrence rates, or not.

The main mechanism behind hernia recurrence is believed to be related to normal growth, which is supposed to lead to traction and eventual detachment of the

[†]References 215, 247, 281, 302, 307, 308.

prosthesis, usually at its posterior-medial aspect.²⁴⁷ The most common clinical manifestations of hernia recurrence are intestinal obstruction and respiratory distress, in that order.^{286,307} Asymptomatic recurrences are not uncommon,^{281,307} nor are patients with multiple recurrences.³⁰⁷ Diagnosis is usually made with a plain chest radiograph; however, sometimes a contrast GI radiograph is necessary. Occasionally, depending on the herniated content, ultrasound, CT, or, more rarely, a contrast enema, may be of help. Hernia recurrence should be surgically repaired, because of the risk for incarceration or strangulation. In select cases of short-term, “small” and stable recurrences, reoperation may be postponed, depending on the patients’ overall condition.³¹³ Given that hernia recurrence is frequently asymptomatic at first, a plain chest radiograph should be performed at least once per year postoperatively in every patient who underwent prosthetic repair.²⁸¹

FUTURE PERSPECTIVES

Since the mid-1990s, much progress has been made on the treatment of CDH. Survival rates consistently hovering around 90% are now commonplace at major referral centers. At the same time, one could say that a formerly fatal illness has been turned into a chronic disease, as morbidity rates have increased in parallel to survival. The challenges ahead relate to both minimizing morbidity and rescuing the cases with extreme pulmonary hypoplasia, which remain the leading cause of death in this disease. These challenges have been the stimuli for some of the most fertile research efforts in pediatric surgery lately. Summarized accounts of some of these efforts will follow, along with a few brief historical notes.

Despite a few anecdotal successes, the results of the actual repair of the hernia in the fetus were disappointing.^{19,20} One of the reasons for the bad results was the fact that the reduction of the hernia increased intra-abdominal pressure, hampering umbilical blood flow, and frequently lead to kinking of the umbilical vein and of the ductus venosus.^{20,314} Wilson and colleagues^{28,315,316} first showed that a complete occlusion of the fetal trachea drastically accelerated fetal lung growth, reversing both the pulmonary hypoplasia and its associated pulmonary vascular abnormalities in experimental CDH, resulting in marked improvements of lung function at birth (Fig. 33-8).^{28,315,316} This led almost immediately to clinical trials, in which fetal tracheal occlusion was accomplished first through open surgery, then videofetoscopically, and then percutaneously.^{31,32,317-320} The tracheal occlusion device is typically removed at birth before occluding the umbilical cord, during an EXIT procedure. Once again, despite successes, at major referral centers results have been significantly worse than that of postnatal care, mostly because of shifting patient selection, postoperative preterm labor, dislodgment of the tracheal occlusion device, erratic secretion of the pulmonary liquid by the fetus, and pulmonary dysfunction in a few patients in whom there was reversal of the lung hypoplasia (the cause of which remains to be determined).^{30-32,318,320} Even so, experimental developments can contribute to refine and

FIGURE 33-8 ■ **A**, Gross necropsy finding in a newborn lamb with experimental congenital diaphragmatic hernia (CDH). The scissors are placed through a defect on the left diaphragm. Abdominal viscera are present in the left hemithorax. The lungs are small and not visible. **B**, Gross necropsy finding in a newborn lamb with experimental CDH and complete tracheal occlusion. The forceps are holding the left diaphragm. Both lungs are markedly enlarged. The left lung has completely reduced the herniated abdominal viscera and has grown into the abdomen, through the diaphragmatic defect. *DH*, Diaphragmatic hernia; *TL*, tracheal ligation. (Reproduced with permission from DiFiore JW, Fauza DO, Slavin R, et al: Experimental fetal tracheal ligation reverses the structural and physiological effects of pulmonary hypoplasia in congenital diaphragmatic hernia. *J Pediatr Surg* 29:248-256, 1994.)

optimize fetal tracheal occlusion in the future—for example, via improvements in patient selection, less invasive methods such as ultrasound-guided or dynamic or reversible techniques, the intrapulmonary delivery of select oncotic agents, and the development of nonhuman primate models.³²¹⁻³²⁶

The acceleration of pulmonary growth observed after fetal tracheal occlusion depends on sustained intrapulmonary distention by retained lung liquid, which is actively secreted by the alveolar-capillary membrane.^{28,315,316} One development of this finding was our demonstration that lung growth can also be accelerated after birth by continuous intrapulmonary distention with a liquid medium, namely PFC, which is bioinert and nonabsorbable by the alveolar-capillary membrane.³⁶ This phenomenon cannot be reproduced in the lungs of adult individuals.³⁷ Apparently, liquid-based pulmonary distention simply accelerates normal growth and cannot induce hyperplasia in mature, developed lungs. Long-term studies in animal models have revealed no deleterious effects of PFC-based lung distention.³²⁷ The first series of neonates to undergo pulmonary distention with PFC under extracorporeal support was presented in 2000, with encouraging results (Fig. 33-9).³⁸ A larger, multicenter study with longer distention times than those allowed by the U.S. Food and Drug Administration in the first series is being pursued.

The concept of lung transplantation in CDH involves the notion that the transplanted lung (or lobe) should maintain the patient only until the native lung

FIGURE 33-9 ■ Plain chest radiographs from a neonate with congenital diaphragmatic hernia, showing the progress of the ipsilateral lung during intrapulmonary distention with a perfluorocarbon (radiopaque) for 7 days. Notice its obvious increase in size, which did not happen in the contralateral lung. (Reproduced with permission from Fauza DO, Hirschl RB, Wilson JM: Continuous intrapulmonary distention with perfluorocarbon accelerates lung growth in infants with congenital diaphragmatic hernia: initial experience. *J Pediatr Surg* 36:1237–1240, 2001.)

contralateral to the hernia develops enough to allow for resection of the graft, so that immunosuppression is no longer necessary. Successful conventional lung transplantations have been performed in CDH in few cases.²⁶ Survival after living donor, reduced lung transplantations has been achieved as well, albeit only experimentally.³²⁸ Chronic donor shortage and the many difficulties yet to be overcome in reduced lung transplantation to newborns render these options of limited, if any, value, at least for the foreseeable future.

Diaphragmatic reconstruction with an autologous engineered construct was first proposed in 2000, and it has since continued to develop experimentally as a viable and potentially improved alternative for diaphragmatic replacement in the neonatal period.^{39,40} Recent data have shown that diaphragmatic repair with an autologous tendon engineered from mesenchymal cells isolated from the amniotic fluid leads to improved mechanical and functional outcomes when compared with an equivalent acellular bioprosthetic repair, or with myogenic cell-based grafts, given a suitable scaffold environment.^{40,41} Cell manufacturing for engineered diaphragmatic replacement has recently proven viable under guidelines mandated by the U.S. Food and Drug Administration.^{42,43} Translation of these findings into clinical practice is hoped for the not too distant future, pending the generation of additional animal safety data as part of the prerequisites for regulatory approval, some of which have already been produced.⁴⁴

Fundamental knowledge and basic aspects of the management of CDH should also continue to improve. A better understanding of the pathogenesis and pathophysiology of this disease is expected. A large, detailed

multicenter study sponsored by the National Institutes of Health aimed at uncovering genetic aspects of CDH has been leading to new germane insights.⁷² The notion of prenatal gene therapy for CDH has started to be explored experimentally in rodent models.³²⁹ The contemporary addition of computer simulation models, including cell-based simulation, could shed additional light on the pathogenesis of CDH.^{330,331} The search for prognostic markers will continue through ever-improving imaging methods such as three-dimensional anatomic measurements via MRI. The role of so-called adjunct therapies and alternative ventilation methods should be better defined.

The role of the Congenital Diaphragmatic Hernia Registry is as important as any of the above mentioned initiatives. Like its pediatric oncology counterparts, this organization, now embracing several tens of centers, has had a significant effect on the understanding and treatment of this disease, and its influence should only continue to grow. The most recent demonstration of the power of such a registry has been the development of a staging system based on defect size measured at the time of repair. It was noted that primary repairs and small patches (types A and B, respectively) were associated with a low incidence of other anomalies and a survival exceeding 96%. Conversely, large patch repairs and diaphragmatic agenesis (type C and D, respectively) had a higher incidence of associated anomalies and lower survival (76% and 58%). Diaphragmatic agenesis associated with a cardiac anomaly had the lowest survival of all at 38%.^{331a} It is hoped that future reports will use this system so that relative severity of different populations can finally be compared.

OTHER DIAPHRAGMATIC ANOMALIES

In addition to “classical” CDH, many other congenital diaphragmatic anomalies have been described. An overview of their location and frequency at different ages can be seen in [Figure 33-10](#).¹⁵⁸ Classical CDH is, by far, the most common diaphragmatic anomaly of the neonatal period. Hiatal hernia seldom manifests prior to adulthood. In this section, only general aspects of these other diaphragmatic anomalies will be briefly discussed.

Diaphragmatic Eventration

The term *eventration* is used to describe an abnormal elevation of the diaphragm. It can be congenital or acquired. Acquired cases, also known as *diaphragmatic paralysis* or *paresis*, usually result from damage to the phrenic nerve, which in turn may be due to traumatic delivery, thoracic surgery, tumors, inflammation, or central nervous system conditions, such as poliomyelitis and Werdnig-Hoffmann disease.³³²⁻³³⁴ In congenital cases, the phrenic nerve is almost always normal. It is often difficult to differentiate a congenital case from one caused by obstetric trauma. Acquired eventration should be suspected whenever there is a history of complications at delivery and/or concomitant signs of injury to the brachial plexus.

In congenital eventration, either the whole diaphragm may be affected or only part of it, usually its dome, which is not a meeting point of embryonic components. Indeed, it is thought that diaphragmatic eventration represents a failure of muscularization of the diaphragm, not a failed fusion of all its embryonic components. Its cause is unknown. It can be present on either side, but is more

frequent on the left. Bilateral cases have been reported.³³⁵ Diaphragmatic thickness and its muscle fiber density vary within a broad spectrum in the eventrated area, going from normal, with practically all fibers present, to very thin, without any fibers. The eventrated portion of the diaphragm does not function. In certain cases, the differentiation with CDH containing a hernia sac is purely arbitrary. Like in CDH, there may be associated pulmonary hypoplasia, intestinal malrotation, and other anomalies in various systems.³³⁶⁻³³⁸

Clinical manifestations also vary within an ample spectrum which, to a certain extent, is analogous to that of CDH. However, presentation after the neonatal period is much more common, and symptoms are usually much less exuberant than in CDH. In older children, (often recurrent) pneumonia may be the first manifestation. Gastrointestinal symptoms, usually obstructive in nature, and failure to thrive are not uncommon. In cases linked to Werdnig-Hoffmann, respiratory distress owing to the eventration may be the initial manifestation of disease.³³³ The patient may also be completely asymptomatic. The diagnosis is typically made with a plain chest radiograph, although sometimes it may have to be confirmed with ultrasonography or fluoroscopy, both of which can also be helpful in an eventual differential with CDH. In the latter two examinations, one should be able to notice paradoxical respiration on the affected area, as long as the patient is not being artificially ventilated.

Symptomatic patients should undergo surgical repair. In asymptomatic patients, surgery is recommended when there is a large eventration or pulmonary function test results are abnormal, given that lung growth may be compromised if the eventration is not treated. In a few patients with an asymptomatic acquired eventration,

FIGURE 33-10 ■ Overall relative incidence and location of different diaphragmatic anomalies at all ages, including children and adults. Bochdalek hernia is, by far, the most common in infants. Hiatal hernia rarely manifests before adulthood. IVC, Inferior vena cava.

there may be variable degrees of recovery of the diaphragmatic function with time and spontaneous reversal of the eventration, so that a so-called conservative treatment may be initially justified, but not for long.

At surgery, plication of the diaphragm with nonabsorbable sutures is usually preferred, but, in select patients, partial resection followed by overlapped reconstruction of the residual diaphragm may be the best option (simple end-to-end suturing commonly leads to recurrence). In right eventrations, most authors prefer to perform the repair through a thoracotomy. In left eventrations, there is some controversy as to whether a thoracotomy or a laparotomy would be the most suitable access. We favor the thoracic access, mostly because it allows for visualization of the branches of the phrenic nerve, which thus can be preserved during diaphragmatic plication. This is particularly relevant in view of the fact that, after plication, there may be at least partial recovery of diaphragmatic function.³³⁹ When a thoracotomy is used, regardless of the side, usually the seventh intercostal space is the one to be opened. An abdominal access may be preferred in certain bilateral cases. Over the last decade or so, thoracoscopic repair has been increasingly favored by most centers, having become the method of choice for many patients; however, it is still unclear whether recurrence rates are comparable to those for open repair, and such techniques are still evolving.³⁴⁰⁻³⁴²

Morgagni Hernia

Morgagni hernia is also known as *retrosternal* or *parasternal hernia*. This kind of diaphragmatic hernia occurs through the parasternal spaces, also called *Morgagni foramina*, or Larrey clefts, which are small, triangular portions of the diaphragm on each side of the inferior limit of the sternum that form as a result of the union between the transverse septum and the thoracic wall. This hernia can occur on both sides, but is more common on the right. Bilateral cases have been reported.^{343,344} If a hernia sac is present, the superior epigastric artery normally stays lateral to it. This hernia is more frequent in adults and in older children. In childhood, this hernia occurs in a proportion of approximately 1:20 in relation to classic CDH.³⁴⁴⁻³⁴⁶ Predisposing factors include obesity and a history of trauma. The hernia is usually asymptomatic. Occasionally, it leads to mild symptoms such as respiratory discomfort, vague gastrointestinal manifestations, or epigastric tenderness. It tends to be symptomatic more often in children than in adults.³⁴⁴ Most of the time, this hernia is diagnosed as an incidental finding of a chest roentgenogram. A lateral radiograph is usually more helpful than an anterior-posterior image, sometimes after a barium swallow, or, more rarely, after contrast enema. Occasionally, ultrasound or CT can be valuable to confirm the diagnosis as well.³⁴⁴

Incarceration of the herniated content is rare. Open repair is frequently performed through a supraumbilical, usually subcostal laparotomy. After hernia reduction and resection of the hernia sac (if present), the diaphragm is sutured to the posterior sheath of the rectus abdominis muscle. A prosthesis is typically not necessary for

diaphragmatic repair. In addition, the laparoscopic approach has been increasingly favored, although it is still unclear how it compares with open repair in the long term.^{347,348}

Various other anomalies can be associated with Morgagni hernia, more frequently cardiac.^{344,346} Intestinal malrotation is somewhat common.³⁴⁴ A Morgagni hernia may be part of the pentalogy of Cantrell, if associated with defects of the inferior aspect of the sternum, of the supraumbilical abdominal wall, and of the pericardium (all of which lead to cardiac ectopia), in addition to a cardiac anomaly.³⁴⁹ In these cases, one usually tries to suture the diaphragm to the sternum and may need to use a prosthesis more frequently than in isolated hernias.

Hiatal Hernia

Hernias through the esophageal hiatus can be divided into four main types: (1) sliding esophageal hernia, the most common, in which the esophagus moves freely through the hiatus, so that the esophagogastric junction may be either in the chest or in the abdomen at different times; (2) paraesophageal hernia, in which the esophagogastric junction remains below the diaphragm and the stomach rolls up into the chest parallel to the esophagus; (3) combined hernia, in which the two previous types coexist; and (4) the controversial congenital short esophagus. Hiatal hernia can manifest as early as the neonatal period; however, most cases first present in adulthood. Vomiting is the most common manifestation, yet patients may often be asymptomatic. The diagnosis is usually made through a contrast upper GI. An upper GI endoscopy is frequently part of the diagnostic evaluation as well. Surgical treatment is the norm, particularly because of the risks of incarceration and strangulation. Through a laparoscopy or a laparotomy, the hernia is reduced, the diameter of the esophageal hiatus is normalized, and a gastroesophageal fundoplication is performed. The treatment of choice for certain cases of short esophagus remains a subject of much debate.

Pericardial Hernia

Pericardial hernia, also known as *hernia of the central diaphragmatic tendon*, is the rarest and least understood of the diaphragmatic defects that can lead to a hernia. In this defect, there is a communication between the peritoneal and pericardial cavities, with or without herniation.³⁵⁰ In general, there is no hernia sac.³⁵⁰⁻³⁵² It has been identified from soon after birth up to late adulthood, with most of the cases diagnosed in neonates.³⁵²⁻³⁵⁴ It is thought that the primary defect affects the transverse septum directly.¹⁵⁸ There are not enough data for typical clinical manifestations to be described. The hernia can be asymptomatic and only incidentally suspected on a plain chest radiograph.^{353,354} Surgical repair through the abdomen is recommended.³⁵³

Diaphragmatic Agenesis

Diaphragmatic agenesis is customarily confused with CDH in which the diaphragmatic defect is particularly

large, especially if the residual posterior diaphragm is not dissected from the abdominal wall. True diaphragmatic agenesis is rare. It is usually unilateral, more common on the left, and rarely bilateral.³⁵⁵⁻³⁵⁷ It is generally identified in the neonatal period, but cases uncovered only in adulthood have been described.^{358,359} It can be associated with multiple other anomalies, especially if bilateral.^{356,360} Clinical manifestations, diagnosis, and treatment are analogous to those of CDH, with the exception of the fact that a prosthesis is always necessary for diaphragmatic closure.³⁵⁹ Survival data are unreliable because in many studies the differentiation with classical CDH is not clear. In general, it is thought that the prognosis is worse than that for classical CDH, given the dimensions of the diaphragmatic defect.

Diaphragmatic Duplication

Diaphragmatic duplication, be it partial or complete, is exceedingly rare.^{361,362} It consists of a fibromuscular membrane that separates the affected hemithorax in two cavities and represents a duplication of the pleuroperitoneal membrane. In most cases, the accessory diaphragm is not innervated by the phrenic nerve. The accessory diaphragm may be eminently muscular and the orthopic diaphragm fibrous, or vice versa.^{363,364} The accessory diaphragm may be in such a location within the chest that the ipsilateral lung is divided in two compartments; it may also be associated with anomalous airways or pulmonary vessels, as well as with partial pulmonary agenesis.³⁶⁴⁻³⁶⁷ Clinically, duplication can cause respiratory distress in the neonatal period, recurring airway infections during childhood, and chronic pulmonary inflammation in adulthood, occasionally with bronchiectasis.^{361,366} Apparently, it can also be asymptomatic.^{365,368} Given that symptoms are non-specific when present, the diagnosis is commonly confirmed only intraoperatively. In the rare cases in which a diaphragmatic duplication was resected, it resulted in improvement of respiratory symptoms. At least one case of association between (right-sided) CDH and diaphragmatic duplication in a neonate has been reported.³⁶⁹

Cribriform Diaphragm

A case of incidental intraoperative finding of a cribriform aspect of the right diaphragm, with several portions of the liver protruding to the chest through the many diaphragmatic defects, has been described in an older patient.³⁷⁰ It is not yet possible to know whether this is another diaphragmatic anomaly, with a distinct embryonic pathogenesis, or an extremely rare variant of CDH, or even simply an acquired diaphragmatic defect.

Upper Esophageal Sphincter
High-Resolution Impedance
Ambulatory pH Monitoring

The esophagus is a muscular tube that starts as the continuation of the pharynx with the upper esophageal sphincter (UES), or cricopharyngeus, and ends with the lower esophageal sphincter at the fundus of the stomach. Knowledge of the anatomy of the esophagus and its relationship with other organs and structures is essential for the surgeon to evaluate the location of lesions seen through use of endoscopy, barium swallow study, or computed tomography; to interpret esophageal function studies; and to safely expose the esophagus during surgery (Fig. 34-1). Similarly, knowledge of foregut embryology is key to the understanding of the pathogenesis of both congenital malformations and acquired diseases of the esophagus.

EMBRYOLOGY

The embryonic esophagus forms when paired longitudinal grooves appear on each side of the laryngotracheal diverticulum. These grooves subsequently grow medially and fuse to form the tracheoesophageal septum. This septum divides the foregut into the ventral laryngotracheal tube and the dorsal esophagus. Incomplete fusion of the two lateral grooves was formerly thought to be the major factor in the pathogenesis of congenital tracheoesophageal fistula, but the anomaly is now attributed to abnormal growth and differentiation of the lung buds. The esophagus is initially short, but it rapidly elongates; the relative final length is attained by the seventh week

of gestation.¹ This is followed by endodermal proliferation, which nearly obliterates the esophageal lumen. Subsequent recanalization occurs by the development of large vacuoles that coalesce. The adult position of the vagal nerves on the lower third of the esophagus results from the unequal growth of the greater and lesser curvature of the stomach, so the left vagus rotates anteriorly and the right vagus posteriorly.

The UES and the most proximal 1 to 2 cm of the cervical esophagus are primarily striated muscle. The striated muscle is derived from the caudal branchial arches and innervated by the vagus nerve and its recurrent laryngeal branches. The UES is made up primarily of the cricopharyngeus muscle, but it is also aided by the inferior pharyngeal constrictors and the circular muscles of the upper esophagus. Studies have indicated that the transition from predominantly striated to predominantly smooth muscle occurs in the proximal 4 to 5 cm of the esophagus and that only 1 cm of the proximal esophagus below the cricopharyngeal sphincter is entirely striated muscle.² In contrast with the proximal portion of the cervical esophagus, the thoracic and abdominal esophagus and the lower esophageal sphincter (LES) consist entirely of smooth muscle and are composed of an inner circular and outer longitudinal layer. A transition zone exists between the smooth and striated muscle components 4 to 8 cm below the cricopharyngeus. The smooth muscle of the lower esophagus arises from the splanchnic mesenchyme and is supplied by nerves of the esophageal plexus derived from neural crest cells.¹

FIGURE 34-1 ■ Classic division of the esophagus and relationships to the cervical and thoracic vertebrae as radiologic landmarks. The approximate lengths and narrowings (arrows) of the esophagus are shown. LES, Lower esophageal sphincter; UES, upper esophageal sphincter.

Esophageal mucosal development in the fetus is complex and undergoes several stages of transformation before birth.³ In early development, the esophagus is lined by a stratified columnar epithelium, which then becomes ciliated; however, at the upper and lower ends of the esophagus a simple columnar epithelium remains. By the third trimester, all the columnar mucosa is subsequently replaced by stratified squamous epithelium throughout the esophagus. By birth, the entire esophagus appears to be completely lined by stratified squamous epithelium and directly abuts the oxyntic mucosa of the stomach below the LES. Any changes to this mucosa in future life are thought to represent acquired metaplasia of the esophageal squamous mucosa, with transformation into cardiac mucosa or intestinal metaplasia as a result of mucosal injury from exposure to gastric juice.

ANATOMY

Cervical Esophagus

The cervical portion of the esophagus is approximately 3 to 5 cm long. It starts below the cricopharyngeus muscle and appears as a continuation of the inferior constrictor muscle of the pharynx. A space between the right and left inferior constrictor muscles posteriorly just above the cricopharyngeus muscle is an area of natural weakening and referred to as Killian triangle, the site where a Zenker diverticulum develops (Fig. 34-2). The beginning of the cervical esophagus is marked by the level of C6, and

FIGURE 34-2 ■ Muscular architecture of the pharyngoesophageal junction, which is the region of the upper esophageal sphincter. The triangular areas of the sparse muscle cover are shown in the scheme. Zenker diverticulum arises from Killian triangle. (Modified from Liebermann-Meffert D: Anatomy, embryology, and histology. In Pearson FG, Deslauriers J, Ginsberg RJ, et al, editors: *Esophageal surgery*, New York, 1995, Churchill Livingstone, pp 1–25.)

the end by the lower border of T1. The cervical esophagus curves slightly to the left as it descends. Anteriorly, it abuts the trachea and larynx and can be dissected off both organs. Posteriorly, the cervical esophagus lies on the vertebral bodies in a prevertebral or retroesophageal space. This space is continuous with the retropharyngeal space superiorly and the posterior mediastinum inferiorly, which is the primary route of descending mediastinitis from oropharyngeal infections. Laterally, the omohyoid muscle crosses the cervical esophagus obliquely, and it is usually necessary to divide this to expose that portion of the esophagus. The carotid sheaths lie laterally, and the lobes of the thyroid and the strap muscles lie anteriorly. The recurrent laryngeal nerves lie in the grooves between the esophagus and the trachea. The right recurrent nerve runs a more lateral and oblique course to reach the groove and is more prone to anatomic variation. Although the surgical approach to the cervical esophagus may be from either side of the neck through an incision along the medial border of the sternocleidomastoid muscle, the left-sided approach is preferred to avoid injury to the more variable course of the right recurrent nerve.

Thoracic Esophagus

The thoracic portion of the esophagus is approximately 18 to 20 cm long (see Fig. 34-1) and starts at the thoracic inlet. In the upper portion of the thorax, it is closely related to the posterior membranous wall of the trachea. This close relationship is responsible for the early spread of cancer of the upper esophagus into the trachea, and it may limit the surgeon's ability to resect such a tumor. Above the level of the tracheal bifurcation, the esophagus courses to the right of the aortic arch and the descending

aorta and then deviates to the left, passing behind the tracheal bifurcation and the left main bronchus. In the lower portion of the thorax, the esophagus remains deviated to the left and passes anteriorly through the diaphragmatic hiatus. There are three natural areas of constriction in the thoracic esophagus: the cricopharyngeus, or UES; the bronchoaortic constriction as it crosses behind the aortic arch and left mainstem bronchus; and the LES.

Unlike the remainder of the gastrointestinal tract, the esophagus does not have a serosal layer and its strength is derived from its mucosa. The thoracic esophagus is covered only by parietal pleura, making this portion the weakest and the most common site of perforation in Boerhaave syndrome, usually on the left side where there is a lack of support from adjacent structures.

The azygos vein is closely related to the right of the esophagus as it ascends from the abdomen and then arches from its paraspinal position over the esophagus and the right main bronchus to enter the superior vena cava.

The thoracic duct ascends behind and to the right of the distal thoracic esophagus between the azygos vein and aorta. At approximately the level of T5, it passes alongside the aorta and ascends on the left side of the esophagus to enter behind the junction of the left internal jugular and subclavian veins. Because of the possibility of disrupting the thoracic duct during its course across the mediastinum during an esophagectomy, ligation of the duct is generally performed low in the chest where it comes through the aortic hiatus.

Abdominal Esophagus

The abdominal portion of the esophagus is approximately 3 to 6 cm long and includes the abdominal portion of the LES. It begins where the esophagus passes through the diaphragmatic hiatus, and it is surrounded by the phrenoesophageal membrane, a fibroelastic ligament that arises from the subdiaphragmatic fascia as a continuation of the transversalis fascia lining the abdomen (Fig. 34-3). The upper leaf of the membrane attaches in a circumferential fashion around the esophagus approximately 1 to 2 cm above the level of the hiatus. The lower leaf of the phrenoesophageal membrane blends with the serosa of the stomach, and its end is marked anteriorly by a prominent fat pad, which corresponds approximately with the

FIGURE 34-3 ■ Attachments of the phrenoesophageal membrane.

gastroesophageal junction. The LES is a zone of high pressure 3 to 4 cm long at the lower end of the esophagus⁴ and does not correspond to any visible macroscopic anatomic landmark either on the external surface of the esophagus or in the endoscopic appearance of the mucosa. Its function is derived from the microscopic architecture of the muscle fibers. The esophageal hiatus is surrounded by the right and left crura, which together form a sling of diaphragmatic skeletal muscle around the esophagus that originates from tendinous bands attached to the anterolateral surface of the first lumbar vertebra (Fig. 34-4). The relative contribution of the right and left crura to this sling is variable. Posterior to the esophagus, the crura are united by a tendinous arch, the median arcuate ligament, which lies just anterior to the aorta.

Structure of the Esophageal Wall

The esophagus is composed of three primary layers: mucosa, submucosa, and muscularis propria. The mucosal layer is normally made of nonkeratinized stratified squamous epithelium. In the distal aspect of the esophagus within the LES, repeated exposure of the squamous epithelium to gastric contents can result in metaplasia to a columnar epithelium known as cardiac mucosa. With further injury and exposure to a specific component of refluxed gastric juice such as bile acids, cardiac mucosa may transform into intestinal metaplasia or Barrett esophagus.

A critical layer within the mucosa for determining the biological behavior of superficial cancers is the muscularis mucosa. This thin, poorly developed layer lies below the basement membrane and above the submucosa. Early tumors that are restricted to the muscularis mucosa are usually confined to the mucosal layer and have little risk of gaining entry into the lymphatics for metastatic spread. When intestinal metaplasia does occur, it is common that the muscularis mucosa is splintered into two separate layers, which can complicate determining the depth of invasion of a superficial tumor.⁵

The submucosa is characterized by a rich lymphatic plexus that extends throughout the esophagus. Lymphatic

FIGURE 34-4 ■ Diaphragm and esophageal hiatus viewed from the abdomen.

collecting branches arise from within the submucosa and pierce the muscularis propria to communicate with regional lymph nodes and the thoracic duct outside of the esophagus. This network of lymphatics allows for significant longitudinal spread of esophageal cancers and a high rate of skip metastases. Clinically, tumor invasion beyond the muscularis mucosa into the submucosa is significant as a result of this lymphatic system, with the rate of regional lymph node metastases increasing from less than 5% with intramucosal tumors up to approximately 50% for submucosal tumors.⁶ Finally, the submucosa of the esophagus also harbors mucous glands that drain into the lumen. These glands are helpful for determining the true extent of the esophagus when metaplasia of the mucosa occurs.

The muscularis propria has an inner circular layer and an outer longitudinal layer. The muscles are striated in the upper portion and transition to completely smooth muscle near the upper third of the esophagus. The longitudinal muscle layer courses down in an elongated spiral pattern, turning approximately 90 degrees as it descends to the stomach. The circular muscle layer is thicker than the longitudinal layer, which also takes on an elliptical or spiral orientation. This arrangement of muscle is responsible for the wormlike drive of peristalsis.

Blood Supply, Lymphatics, and Innervation

The cervical portion of the esophagus receives its main blood supply from the inferior thyroid artery. The thoracic portion receives blood from the bronchial and esophageal arteries. Seventy-five percent of individuals have one right-sided and two left-sided bronchial arteries, and usually two esophageal branches arise directly from the aorta. The blood supply of the abdominal portion of the esophagus comes from the ascending branch of the left gastric artery and from the right and left inferior phrenic arteries (Fig. 34-5). After the vessels have entered the muscular wall of the esophagus, branching occurs at right angles to provide an extensive longitudinal vascular plexus. The rich blood supply provided by this vascular plexus allows mobilization of the esophagus from the stomach to the aortic arch without causing ischemic injury.⁷

The capillaries of the esophagus drain into a submucosal and periesophageal venous plexus, from which the esophageal veins originate. In the cervical region, the esophageal veins empty into the inferior thyroid vein; in the thoracic region, they empty into the bronchial, azygos, or hemiazygos veins; and in the abdominal region, they empty into the coronary vein (Fig. 34-6).

The lymphatic channels are located almost exclusively below the muscularis mucosa in the submucosa of the esophagus, constituting a dense and interconnected plexus with more lymph vessels than blood capillaries (Fig. 34-7). Lymph flow in the submucosal plexus runs in a longitudinal direction, and after the injection of a contrast medium, the longitudinal spread is six times that of the transverse spread. In the upper two thirds of the esophagus, the lymphatic flow is mostly cephalad; in the

FIGURE 34-5 ■ Arterial blood supply of the esophagus. (Modified from Rothberg M, DeMeester TR: Surgical anatomy of the esophagus. In Shields TW, editor: *General thoracic surgery*, ed 3, Philadelphia, 1989, Lea & Febiger, p 84.)

FIGURE 34-6 ■ Venous drainage of the esophagus. (Modified from Rothberg M, DeMeester TR: Surgical anatomy of the esophagus. In Shields TW, editor: *General thoracic surgery*, ed 3, Philadelphia, 1989, Lea & Febiger, p 85.)

FIGURE 34-7 ■ Lymphatic drainage of the esophagus. (From DeMeester TR, Barlow AP: Surgery and current management for cancer of the esophagus and cardia: Part 1. *Curr Probl Surg* 25:475–531, 1988.)

lower third, it is mostly caudad. In the thoracic portion of the esophagus, the submucosal lymph plexus extends over a long distance in a longitudinal direction before penetrating the muscle layer to enter lymph vessels in the adventitia. As a consequence of this nonsegmental lymph drainage, the lymphatic spread of tumor cells can extend for a considerable distance superiorly and inferiorly within the submucosal lymphatics before the cells pass through lymphatic channels in the muscularis and into the regional lymph nodes. There is a high rate of skip metastases in esophageal cancer because of this arrangement. By contrast, the cervical esophagus has a more segmental lymph drainage into the regional lymph nodes, and as a result, tumors in this portion of the esophagus have less submucosal extension.

Lymph from the cervical esophagus drains into the paratracheal and deep cervical lymph nodes, whereas lymph from the upper thoracic esophagus flows mainly into the paratracheal lymph nodes. The lymph from the lower thoracic esophagus drains into the subcarinal and inferior pulmonary nodes. Lymph from the distal thoracic and abdominal portion of the esophagus drains into the parahiatal and perigastric nodes.¹

FIGURE 34-8 ■ Innervation of the esophagus. (Modified from Rothberg M, DeMeester TR: Surgical anatomy of the esophagus. In Shields TW, editor: *General thoracic surgery*, ed 3, Philadelphia, 1989, Lea & Febiger, p 85.)

The parasympathetic innervation of the pharynx and esophagus is provided mainly by cranial nerve X or the vagus nerves. The constrictor muscles of the pharynx receive branches from the pharyngeal plexus, which is located on the posterior lateral surface of the middle constrictor muscle and is formed by pharyngeal branches of the vagus nerve, with a small contribution from cranial nerves IX and XI. The cricopharyngeal sphincter and the cervical portion of the esophagus receive branches from both right and left recurrent laryngeal nerves originating from the vagus nerves (Fig. 34-8). Damage to these recurrent nerves interferes not only with the movement of the vocal cords but also with the function of the cricopharyngeal sphincter and the motility of the cervical esophagus, predisposing the patient to pulmonary aspiration on swallowing. The upper thoracic esophagus receives innervation from the left recurrent laryngeal nerve and both vagus nerves. As the right and left vagus nerves descend into the mediastinum, they join the outer surface of the esophagus. The esophageal plexus, which is formed by the branches of the right and left vagus nerves and thoracic sympathetic chain, lies on the anterior and posterior walls of the esophagus and innervates the lower thoracic portion.⁸ The branches of the plexus coalesce into the left (anterior) and right (posterior) vagal trunks.

Afferent visceral sensory fibers from the esophagus end without synapse in the first four segments of the thoracic spinal cord by a combination of sympathetic and vagal pathways. These pathways are also occupied by afferent visceral sensory fibers from the heart, which explains the similarity of symptoms in esophageal and cardiac diseases.

PHYSIOLOGY

To comprehend the mechanics of alimentation, it is useful to visualize the gullet as a series of pumps and valves. In the pharyngeal segment, the tongue and pharyngeal muscle function as pumps, whereas the soft palate, the epiglottis, and the cricopharyngeus serve as the valves that regulate flow. In the esophageal segment, the esophageal body functions as the pump to propel the food bolus, whereas the LES serves as a valve to allow transport into the stomach and to prevent the flow of gastric contents back into the esophagus.

The Swallowing Mechanism

Swallowing can be started at will, or it can be reflexively elicited by the stimulation of the anterior and posterior tonsillar pillars or the posterior lateral walls of the hypopharynx. The afferent sensory nerves of the pharynx are the glossopharyngeal nerves and the superior laryngeal branches of the vagal nerves. Once it is aroused by stimuli entering through these nerves, the swallowing center in the medulla coordinates the complete act of swallowing by discharging impulses through cranial nerves V, VII, X, XI, and XII and the motor neurons of C1 through C3. Discharges through these nerves always occur in a specific pattern and last for approximately 0.5 second. Little is known about the swallowing center except that it can trigger swallowing after a variety of different inputs. Once it is triggered, the swallow response is always a rigidly ordered pattern of outflow neurogenic impulses.

FIGURE 34-9 ■ Sequence of events during the oropharyngeal phase of swallowing. (From DeMeester TR, Stein HJ, Fuchs KH: Physiologic diagnostic studies. In Zuidema GD, Orringer MB, editors: *Shackelford's surgery of the alimentary tract*, ed 3, vol 1, Philadelphia, 1991, Saunders, p 95.)

The act of alimentation requires the passage of food and drink from the mouth into the stomach. Food is taken into the mouth in a variety of bite sizes, after which it is broken up by the teeth, mixed with saliva, and lubricated. When food is ready for swallowing, the tongue, acting as a pump, moves the bolus into the posterior oropharynx and forces it into the hypopharynx (Fig. 34-9). Concomitantly with the posterior movement of the tongue, the soft palate is elevated, thereby closing the passage between the oropharynx and nasopharynx. With the initiation of the swallow, the hyoid moves superiorly and anteriorly, thereby elevating the larynx and enlarging the retropharyngeal space. At the same time, the epiglottis covers the laryngeal inlet to prevent aspiration.

During swallowing, the pressure in the hypopharynx rises abruptly to 60 mm Hg as a result of the backward movement of the tongue and contraction of the posterior pharyngeal constrictors. A sizable pressure difference develops between the hypopharyngeal pressure and the subatmospheric midesophageal or intrathoracic pressure (Fig. 34-10). This pressure gradient speeds the movement of food from the hypopharynx into the esophagus when the cricopharyngeus or UES relaxes. The bolus is both propelled by the peristaltic contraction of the posterior pharyngeal constrictors and sucked into the thoracic esophagus by this pressure gradient.

Critical to receiving the bolus is the compliance of the cervical esophageal muscle and the timing and degree of relaxation of the UES. Abnormalities of compliance and UES opening can result in pharyngeal dysphagia. During the transfer of the bolus from the mouth into the esophagus, the UES is mechanically pulled open. Elevation of

FIGURE 34-10 ■ Resting pressure profile of the foregut showing the pressure differential between the atmospheric pharyngeal pressure (P) and the less-than-atmospheric midesophageal pressure (E) and the greater-than-atmospheric intragastric pressure (G), with the interposed high-pressure zones of the cricopharyngeus (C) and the distal esophageal sphincter (DES). The necessity for relaxation of the cricopharyngeus and DES pressure to move a bolus into the stomach is apparent. Esophageal work occurs when a bolus is pushed from the midesophageal area with a pressure that is less than atmospheric (E) and into the stomach, which has a pressure that is greater than atmospheric (G). (From Waters PF, DeMeester TR: Foregut motor disorders and their surgical management. *Med Clin North Am* 65:1235-1268, 1981.)

the larynx by muscles attached to the hyoid bone pulls the UES open at the time muscle relaxation of the UES occurs. This is an active relaxation caused by a reduction in the tone of the tonic cricopharyngeus muscle, and it is dependent on a neurologically mediated reflex. This is an all-or-nothing event; partial relaxation does not normally occur. The UES closes within 0.5 second of the initiation of the swallow, with a postrelaxation contraction pressure that is approximately twice the resting pressure of 30 mm Hg. The postrelaxation contraction continues down the esophagus as a peristaltic wave (Fig. 34-11). The high closing pressure and the initiation of the peristaltic wave prevent reflux of the bolus from the esophagus into the pharynx. After completion of the swallow, the pressure of the UES returns to its normal resting pressure.

The pharyngeal activity in swallowing initiates the esophageal phase of swallowing. Because of the helical arrangement of its circular muscles, the body of the esophagus functions as a worm-drive propulsive pump,

FIGURE 34-11 ■ Intraluminal esophageal pressures in response to swallowing. (From Waters PF, DeMeester TR: Foregut motor disorders and their surgical management. *Med Clin North Am* 65:1235-1268, 1981.)

and it is responsible for transmitting a bolus of food into the stomach. With the act of swallowing, the longitudinal muscle of the esophageal body shortens, thus enlarging the lumen to accept the bolus (the “on response”), after which the circular smooth muscle contraction forms the peristaltic wave (the “off response”). During the esophageal phase of swallowing, the bolus is moved into the stomach over a gradient of 12 mm Hg (i.e., from a negative intrathoracic pressure environment of -6 mm Hg to a positive intra-abdominal pressure environment of $+6$ mm Hg). Effective and coordinated smooth muscle function in the lower two thirds of the esophageal body is important to allow this movement to occur.

The peristaltic wave generates an occlusive pressure that varies from 30 to 120 mm Hg. The wave rises to a peak in 1 second, remains at the peak for approximately 0.5 second, and then subsides in approximately 1.5 seconds. The whole course of the rise and fall of an occlusive contraction may occupy one point in the esophagus for 3 to 5 seconds.^{9,10} The peak of the primary peristaltic contraction moves down the esophagus at a rate of 2 to 4 cm per second and reaches the distal esophagus approximately 9 seconds after swallowing starts. A consecutive swallow after 20 seconds produces a similar primary peristaltic wave; however, if repetitive swallowing occurs sooner, the esophagus becomes unresponsive (*deglutitive inhibition*).

To be effective, peristaltic contractions must be of sufficient amplitude to occlude the esophageal lumen and sufficiently organized in a peristaltic waveform to propel a bolus toward the stomach. Low-amplitude contractions that do not occlude the lumen merely indent a semisolid bolus rather than propel it, and simultaneous contractions throughout the body of the esophagus result in splitting the bolus or even propelling it orally, which can be observed on a barium esophagram as bolus segmentation or cephalic escape.

Clinically, defects in peristalsis occur in three broad categories, depending on which major feature is the most impaired. First, there is a neural abnormality that results in the defective organization of the peristaltic wave; this is recognized by the presence of simultaneous contractions with a loss of the peristaltic sequence and results in typical primary motility disorders (e.g., diffuse esophageal spasm). The second category defect is evident when there is a reduction of the amplitude of the contraction but the peristaltic sequence remains; this is usually the result of muscle damage and the formation of fibrous tissue within the muscle. Examples include end-stage gastroesophageal reflux disease and connective tissue disorders such as scleroderma. The third category defect results from altered anatomy of the esophageal body. A loss in the efficiency of the peristaltic sequence can result when the esophagus is not anchored distally (as occurs with a large paraesophageal hernia), which can result in the appearance of an accordion esophagus on a barium swallow esophagram with ineffective clearance of barium.

Lower Esophageal Sphincter

The LES represents the barrier that confines the gastric juice to the stomach and protects the acid-sensitive

squamous esophageal mucosa from injury by refluxed gastric juice. As is true for any valve, failure of the LES can occur in two completely opposite ways, which lead to two distinct clinical disease entities. Regardless of the type of LES failure, the secondary effects are produced proximally in the esophagus. Failure of the LES to relax or to open appropriately leads to the inability of the esophagus to propel food into the stomach, esophageal distention, and the condition known as *achalasia*. On the other hand, failure of the LES to remain closed leads to an increased exposure of the squamous epithelium to gastric juice and the condition known as *gastroesophageal reflux disease* (GERD).

The LES has no anatomic landmarks and cannot be seen endoscopically; it is identified on manometry as a rise in pressure over gastric baseline pressure. This high-pressure zone is normally present except in two situations: (1) after a swallow, when it is momentarily dissipated or relaxes to allow passage of food into the stomach; and (2) during a belch, when it allows gas to be vented from a distended fundus. The common denominator for virtually all episodes of gastroesophageal reflux is the loss of this normal high-pressure zone or barrier. When the barrier is absent, resistance to the flow of gastric juice from an environment of higher pressure (the stomach) to an environment of lower pressure (the esophagus) is lost. In early GERD, this is usually caused by a transient loss of the barrier. In advanced GERD, there is usually a permanent loss of the barrier.¹¹

Three characteristics of the LES or high-pressure zone maintain its function as a barrier to intragastric and intra-abdominal pressure challenges. Two of these characteristics—the overall length and pressure of the LES—work together and depend on each other to provide resistance to the flow of gastric juice from the stomach into the esophagus.¹² The shorter the overall length is, the higher the pressure must be for the LES to maintain sufficient resistance to remain competent (Fig. 34-12). Consequently, the effect of a normal LES pressure can be nullified by a short overall LES length, and the effect of a normal overall LES length can be nullified by a low LES pressure. For practical purposes, the

FIGURE 34-12 ■ The relationship of the lower esophageal sphincter (LES) pressure (measured at the respiratory inversion point) and overall LES length with the resistance to the flow of fluid through the barrier. Note that the shorter the overall length of the high-pressure zone is, the higher the pressures must be to maintain sufficient resistance to remain competent. *Competent*, No flow; *incompetent*, flow of varied volumes.

pressure of the LES is measured at a single point, but in actuality, pressure is applied over the entire length of the LES; this allows the computer formation of a three-dimensional image of the LES or barrier (Fig. 34-13). The volume of this image reflects the resistance of the LES to the flow of fluid through it, which is called the *sphincter pressure vector volume*. A calculated volume below that of the fifth percentile of normal resting subjects indicates a permanently defective LES.¹³ A fundamental principle for surgeons to understand is that the length of the barrier or LES is critical to its function.

Foreshortening of LES length occurs naturally with gastric filling as the terminal esophagus is “taken up” by the expanding fundus (Fig. 34-14)¹⁴; this is similar to the shortening of the neck of a balloon as it is inflated. With excessive gastric distention (e.g., with overeating), the length of the LES shortens to a critical point at which it gives way, the pressure drops precipitously, and reflux

FIGURE 34-13 ■ A graphic illustration of how a three-dimensional computerized image of the lower esophageal sphincter can be constructed by measuring the pressure of the high-pressure zone in four quadrants at 0.5-cm intervals over the entire length of the zone. *RIP*, Respiratory inversion point. (From Stein HJ, DeMeester TR, Naspetti R, et al: Three-dimensional imaging of the lower esophageal sphincter in gastroesophageal reflux disease. *Ann Surg* 214:374–384, 1991.)

FIGURE 34-14 ■ The relationship between overall sphincter length and gastric distention with increasing volumes of water. (From Mason RJ, Lund RJ, DeMeester TR, et al: Nissen fundoplication prevents shortening of the sphincter during gastric distention. *Arch Surg* 132:719–726, 1997.)

FIGURE 34-15 ■ The relationship between resting lower esophageal sphincter (LES) pressure measured by manometry and LES length when applied pressure or “sphincter squeeze” is kept constant. Analysis was made with a model of the LES high-pressure zone. Note that as the LES length decreases, the pressure recorded within the LES decreases only slightly until a length of 2 cm is reached, when LES pressure drops precipitously and its competency is lost. (From Pettersson GB, Bombeck CT, Nyhus LM: The lower esophageal sphincter: mechanisms of opening and closure. *Surgery* 88:307–314, 1980.)

occurs (Fig. 34-15).¹⁵ If the length of the LES is permanently shortened, then further shortening caused by the normal gastric distention with normal-volume meals results in postprandial reflux. In this situation, competency of the barrier is an ever-constant clinical problem. The observation that gastric distention results in shortening of the LES down to a critical length so that the pressure dissipates, the lumen opens, and reflux occurs provides a mechanical explanation for transient LES relaxations without invoking a neuromuscular reflex. If only the LES pressure and not its length is measured (e.g., with a Dent sleeve), the event appears as a spontaneous relaxation of LES pressure.¹⁶ In reality, it is the progressive shortening of the LES rather than the transient LES relaxations that results in the loss of LES pressure.

Variations in the anatomy of the cardia, from a normal acute angle of His to an abnormal dome architecture of a sliding hiatal hernia, influence the ease with which the sphincter is shortened by gastric distention. A hernia can result from the pulsion force of abdominal pressure on the esophageal hiatus or from the traction produced by inflammatory fibrosis of the esophageal body. The resulting alteration in the geometry of the cardia places the sphincter at a mechanical disadvantage in maintaining its length with progressive degrees of gastric distention. Greater gastric distention is necessary to open the barrier in patients with an intact angle of His than in those with a hiatal hernia.¹⁷ The reason is that the dome or funnel shape of a hiatal hernia allows the wall tension forces that pull open the barrier with gastric distention to be more effectively applied to the gastroesophageal junction,¹⁸ and it accounts for the common association of a hiatal hernia with GERD. Kahrilas and colleagues¹⁹ demonstrated this

mechanical disadvantage by studying the effect of intra-gastric air infusion on the number of transient LES relaxations or “shortenings” per hour. Patients with hiatal hernias had significantly more transient LES relaxations per hour than did control subjects without hernias. The reduction in length became significant 20 to 30 minutes after the beginning of air infusion and occurred in a distal to cephalad direction before a loss of LES pressure was observed.

The third characteristic of the LES high-pressure zone is its position. A portion of the overall length of the high-pressure zone is normally exposed to the positive intra-abdominal pressure environment and is commonly referred to as the abdominal length of the LES.²⁰ During periods of increased intra-abdominal pressure, the resistance of the LES would easily be overcome if its position were such that abdominal pressure is unable to be applied equally to the LES and the stomach.^{21–23} This is analogous to sucking on a soft soda straw immersed in a bottle of liquid; the positive hydrostatic pressure of the fluid and the negative pressure inside the straw from sucking cause the straw to collapse instead of allowing the liquid to flow up the straw in the direction of the negative pressure. If the LES is positioned so that the abdominal length is inadequate, it cannot collapse in response to applied positive intra-abdominal pressure. On the other hand, intra-gastric pressure would be augmented by the applied positive intra-abdominal pressure, and the sphincter pressure would be easily overcome; the negative intrathoracic pressure will encourage reflux to occur. More than 1 cm of the LES needs to be exposed to the abdominal pressure environment for it to respond effectively to changes in intra-abdominal pressure.

If, in the fasting state, the LES has an abnormally low pressure, a short overall length, or a minimal length exposure to the abdominal pressure environment, the result is a permanent loss of resistance with unhampered reflux of gastric contents into the esophagus; this is known as a permanently defective barrier or LES. The most common consequence of a permanently defective LES is increased esophageal exposure to gastric juice, which results in inflammatory injury to the mucosa and ultimately to the muscularis propria of the esophageal body, thereby causing a reduced contraction amplitude of the esophageal body and interrupted or dropped peristaltic sequences. If the reflux is not brought under control, the progressive loss of effective esophageal clearance results in an ever-increasing esophageal exposure to gastric juice, with further organ injury (Fig. 34-16).^{24,25}

Causes and Consequences of the Failure of the Gastroesophageal Barrier

Early GERD is initiated by increased transient losses of the barrier as a result of gastric overdistention from excessive air and food ingestion.^{11,26} The tension vectors produced by gastric wall distention pull on the gastroesophageal junction, which results in the terminal esophagus being “taken up” into the stretched fundus, thereby reducing the length of the LES. With overeating, a critical length is reached (usually approximately 1 to 2 cm) at which the sphincter gives way; its pressure drops

FIGURE 34-16 ■ Schema of the progression of gastroesophageal reflux disease (GERD). Initially, esophageal acid exposure occurs only after meals and when the patient is in the upright, awake position, as a result of the transient losses of the barrier. With inflammatory injury to the lower esophageal sphincter (LES), the barrier becomes permanently defective, and an increase in the esophageal acid exposure occurs with the patient in the supine position, whereas gravity and the esophageal body effectively clear the refluxed acid during the day when the patient is upright. Inflammatory injury to the esophageal body from supine acid exposure results in the loss of esophageal body clearance function and increased esophageal acid exposure during the day and night; this is known as bipositional reflux.

precipitously, and reflux occurs (see Fig. 34-14). If the swallowed air is vented, gastric distention is reduced, the length of the LES is restored, and competency returns until subsequent distention again shortens it and further reflux occurs. Aerophagia is common in patients with GERD because they swallow their saliva more frequently to neutralize the acidic gastric juice that is refluxed into the esophagus.²⁷ Together, the actions of overeating and air swallowing result in the common complaint of postprandial bloating, repetitive belching, and heartburn in patients with early GERD. The high prevalence of the disease in the Western world is thought to be a result of the eating habits of Western society. Gastric distention from overeating, along with delayed gastric emptying resulting from the increased ingestion of fatty foods, leads to prolonged periods of postprandial gastric distention with shortening of the LES and repetitive transient loss of the barrier. Surgical correction with a fundoplication prevents the shortening of the barrier with progressive degrees of gastric distention by diverting the forces produced by gastric wall tension that pull on the gastroesophageal junction.¹⁵

In advanced GERD, permanent loss of sphincter length occurs from inflammatory injury that extends from the mucosa into the muscular layers of the LES. Fletcher and colleagues²⁸ showed that in the fasting state, there is a persistent region of high acidity in the area of the gastroesophageal junction and this region of acidity migrates 2 cm proximally after meals.²⁹ This migration occurs from distention of the stomach with eating and pulling apart of the distal high-pressure zone or LES, thus allowing the area of high acidity to move proximal to the squamocolumnar junction. This proximal movement exposes the distal esophageal squamous mucosa to acid and results in the formation of cardiac mucosa.

Cardiac mucosa is an acquired mucosa that replaces chronically injured squamous mucosa in the terminal esophagus.³⁰ The inflammatory process can extend into the muscular layer of the LES, thereby resulting in muscle cell injury with permanent shortening of the high-pressure zone or LES and a concomitant reduction in the amplitude of the high-pressure zone or barrier pressure.³⁰⁻³² A defective barrier is recognized when the length or pressure of the LES measured during the fasting state is below the 2.5 percentile of normal.³³

For clinicians, the finding of a permanently defective LES has several implications. First, symptoms in patients with a defective LES can be difficult to manage, and mucosal damage may persist with medical therapy.³⁴ Surgery is usually required to achieve consistent long-term symptom relief in these patients to restore a gastroesophageal barrier and interrupt the natural history of the disease. It has been shown repeatedly that a laparoscopic Nissen fundoplication can consistently restore the length and pressure of the LES to normal parameters.³⁵ Newer techniques of sphincter augmentation such as with a magnetic bracelet is an alternative means of restoring the LES that is gaining in popularity.³⁶ Second, a permanently defective LES is commonly associated with reduced contractility and abnormal wave progression of the esophageal body³⁷; this makes the clearance of reflux acid difficult and leads to excessive esophageal exposure to acid. For this reason, careful evaluation of the esophageal body is critical in the evaluation for antireflux surgery for potential tailoring of the operation with a partial fundoplication. Third, a permanently defective LES and the loss of effective esophageal clearance lead to increased esophageal exposure to gastric juice with mucosal injury and the potential for Barrett metaplasia, repetitive regurgitation, aspiration, and pulmonary fibrosis. Without reestablishing a barrier, chronic use of acid suppression therapy may simply mask the symptoms due to modification of the pH; however, in the setting of a structurally defective LES, reflux will continue unabated.³⁸

EVALUATION OF ESOPHAGEAL FUNCTION

A thorough understanding of the patient's underlying anatomic and functional deficits is fundamental to the successful treatment of esophageal disease. The diagnostic tests used to evaluate the esophagus are those used to visualize structural abnormalities, to detect functional abnormalities, and to measure esophageal exposure to gastric juice. At the authors' center, a panel of four diagnostic tests is used routinely in the evaluation of known or suspected reflux disease: barium esophagram, upper endoscopy, high-resolution esophageal manometry, and ambulatory pH monitoring.

Radiographic Evaluation

Radiographic assessment of the anatomy and function of the esophagus and stomach is one of the more important aspects of the esophageal evaluation, provided the surgeon has a working knowledge of esophageal physiology. Classically, the barium esophagram has been described as a

road map for the esophagus. The first diagnostic test in patients with suspected esophageal disease should be a barium swallow that includes a full assessment of the stomach and the duodenum.³⁹ Video recording of the study greatly aids in the evaluation by providing the surgeon with a real-time visualization of bolus transport and the size and reducibility of the hiatal hernia. The study also provides anatomic information, such as the presence of obstructing lesions and structural abnormalities of the foregut.

The pharynx and the UES are evaluated in the upright position, with the performance of an assessment of the relative timing and coordination of the events of pharyngeal transit.⁴⁰ This includes oropharyngeal bolus transport, pharyngeal contraction, opening of the pharyngoesophageal segment, and degree of airway protection during swallowing. It readily identifies a diverticulum, stasis of the contrast medium in the valleculae, cricopharyngeal bar, or narrowing of the pharyngoesophageal segment. These are anatomic manifestations of neuromuscular disease and result from the loss of muscle compliance from the deinnervation of the skeletal muscle of the pharynx and the cervical esophagus.⁴¹

The assessment of peristalsis on video esophagography often adds to or complements the information obtained by esophageal manometry. Esophageal clearance is optimally assessed by observing several individual swallows of barium with the patient in both upright and supine positions; the study can be performed with both liquid and solid bolus material. During normal swallowing, a primary peristaltic wave is generated that completely strips the bolus out of the esophagus and into the stomach. Residual material rarely stimulates a secondary peristaltic wave; rather, an additional pharyngeal swallow is usually required.

The protocol developed and used at the authors' institution has previously been reported.⁴² Normal subjects in the prone position can clear at least three of five 10-mL liquid barium boluses with one swallow and have only one episode of proximal escape or distal retention of a barium bolus with the five swallows. Normal subjects can clear a solid barium bolus with four or fewer swallows in the upright position. Motility disorders with disorganized or simultaneous esophageal contraction give a segmented appearance to the barium column. This can often give a beading or corkscrew appearance to the barium within the esophagus. In patients with dysphagia, the use of a barium-impregnated marshmallow, piece of bread, or hamburger can identify an esophageal transport disturbance that is not evident on the liquid barium study.

A hiatal hernia is present in a high percentage of patients with gastroesophageal reflux.¹¹ A hiatal hernia is best demonstrated with the patient in the prone position; the increased intra-abdominal pressure produced in this position promotes displacement of the hernia above the diaphragm. The hiatal hernia is an important component of the underlying pathophysiology of reflux. A large (>5 cm) or irreducible hiatal hernia suggests a shortening of the esophagus, and a paraesophageal hernia can result in dysphagia. Reflux is not easily seen on video esophagography, and spontaneous reflux of contrast from the stomach to the esophagus does not necessarily predict abnormal acid exposure on pH monitoring. Moreover,

failure to observe reflux during a video esophagram does not indicate the absence of disease.

A full-column technique with distention of the esophageal wall can discern extrinsic compression of the esophagus, and a fully distended esophagogastric region is necessary to identify narrowing from a Schatzki ring, stricture, or obstructing lesion. Mucosal relief or double-contrast films can be obtained to enhance the detection of small neoplasms, esophagitis, and varices. Assessment of the stomach and duodenum during the barium study is helpful for the evaluation of the patient with esophageal symptoms. A gastric or duodenal ulcer, a neoplasm, or poor gastroduodenal transit can mimic many of the symptoms that are suggestive of an esophageal disorder.

Endoscopic Examination

Endoscopic evaluation of the esophagus is essentially the physical examination of the foregut. It is a critical part of the assessment of a patient with esophageal disease and is indicated even if the video esophagogram is normal. A barium study obtained before esophagoscopy is helpful to the endoscopist by directing attention to locations of subtle change and alerting the examiner to such potential danger spots as a cervical vertebral osteophyte, an esophageal diverticulum, a deeply penetrating ulcer, or a carcinoma. Regardless of the radiologist's interpretation of an abnormal finding, each structural abnormality of the esophagus should be examined visually with an endoscope.

During every endoscopic examination, the locations of three specific landmarks are routinely obtained relative to the front incisors: the squamocolumnar junction, gastroesophageal junction, and the diaphragmatic crura. The crura are usually evident, and their location can be confirmed by having the patient sniff. The gastroesophageal junction is the location at which the gastric rugal folds meet the tubular esophagus; it is normally aligned with the squamocolumnar junction. The squamocolumnar junction is the location at which the velvet and darker rose-colored columnar epithelium changes to the lighter squamous epithelium. When this junction is not clear, narrow band imaging is extremely helpful in distinguishing columnar from squamous mucosa, a feature that is standard on all modern endoscopic systems. Particular effort should be made to detect esophagitis and Barrett columnar epithelium-lined esophagus when GERD is suspected.

Barrett esophagus is a condition in which the tubular esophagus is lined with columnar epithelium as opposed to the normal squamous epithelium. On histologic examination, it appears as columnar mucosa with goblet cells and is called intestinal metaplasia. It is suspected at endoscopy when there has been separation of the squamocolumnar junction from the gastroesophageal junction. When columnar metaplasia is observed, it must be biopsied to confirm the presence of intestinal metaplasia to make the diagnosis of Barrett esophagus; the finding of cardiac metaplasia without goblet cells does not meet this criterion. Early metaplasia is often manifested as an irregular or eccentric squamocolumnar junction. Routine four-quadrant biopsies with jumbo forceps are necessary

every 2 cm of columnar metaplasia. In addition, the likelihood of identifying goblet cells is greatest at the cephalad portion of a columnar segment, especially at the squamocolumnar junction.⁴³ Barrett esophagus is susceptible to ulceration, bleeding, stricture formation, and malignant degeneration. The earliest histologic sign of malignant degeneration is high-grade dysplasia or intramucosal adenocarcinoma. These dysplastic changes have a patchy distribution, so a minimum of four biopsy specimens every 2 cm should be taken from the Barrett mucosa-lined portion of the esophagus. A study of intramucosal adenocarcinomas arising in patients with Barrett esophagus showed that most of the tumors arose in the distal Barrett segment, closer to the stomach.⁴⁴

Abnormalities of the cardia or gastroesophageal junction can be visualized by retroflexion of the endoscope and provide a complementary assessment regarding the competency of the gastroesophageal barrier. Hill and colleagues⁴⁵ have graded the appearance of the gastroesophageal valve from I to IV according to the degree of unfolding or deterioration of the normal architecture (Fig. 34-17). This is a commonly used grading system that has allowed endoscopists to maintain uniformity in their reporting. The Hill grade correlates well with the competence of the gastroesophageal barrier; that is, increasing acid exposure is prevalent in patients with a worsening Hill grade.⁴⁶

A hiatal hernia is diagnosed by observing separation of the gastroesophageal junction from the crura. By definition, a hiatal hernia is present when at least 2 cm of the top of the rugal folds has migrated above the margins of the diaphragmatic crura. A prominent sliding hiatal hernia is frequently associated with GERD. When a hernia is observed, particular care is taken to exclude a gastric Cameron ulcer or gastritis within the herniated stomach.

As the endoscope is slowly withdrawn, the esophagus is examined again, and biopsy samples are taken. The location of the cricopharyngeus is identified, and the larynx and vocal cords are visualized. Acid reflux may result in inflammation of the larynx. Vocal cord movement should also be recorded, both as a reference for subsequent surgery and as an assessment of the patient's ability to protect the airway.

Esophageal Manometry

Fundamental to the evaluation of a patient with benign esophageal disease is the assessment of esophageal contractility and sphincter function. Manometry is indicated whenever an abnormality of the esophagus is suggested by the symptoms of dysphagia, odynophagia, chest pain, heartburn, and regurgitation. It is particularly necessary to confirm the diagnosis of specific primary esophageal motility disorders, such as achalasia, diffuse esophageal spasm, nutcracker esophagus, or hypertensive LES. It can also identify ineffective esophageal motility abnormalities that result from GERD and systemic disease, such as scleroderma, dermatomyositis, polymyositis, or mixed connective tissue disease. In patients with symptomatic GERD, esophageal manometry can identify a mechanically defective LES and evaluate the adequacy of the esophageal body contraction amplitudes and waveform. Finally, manometry is mandatory for accurate placement of an ambulatory pH monitor in relationship to the upper border of the LES.

High-resolution esophageal manometry has become standard technology and represents an improvement in methodology that leads to a more detailed data collection and simpler data interpretation. The concept behind this technology is that by vastly increasing the number of sensors and reducing the space between the sensors, it

FIGURE 34-17 ■ Endoscopic Hill grading of the gastroesophageal valve. (From Hill LD, Kozarek RA: The gastroesophageal flap valve. *J Clin Gastroenterol* 28:194–197, 1999.)

can provide representation of the entire pressure profile along the esophagus from the pharynx to the proximal stomach without the need to reposition or to pull back the catheter as in conventional manometry.

The most commonly used high-resolution system is a solid-state manometric assembly with 36 circumferential sensors spaced at 1-cm intervals (ManoScan, Covidien). These transducers detect the pressure over a length of 25 mm in each of 12 radially dispersed sectors. The recorded pressure at each sector is then averaged, making each of the 36 sensors a circumferential pressure detector with the extended frequency response characteristic of solid-state manometric systems and free of the hydrostatic influence characteristic of water-perfused systems. The increased number of circumferential pressure sensors results in a vastly greater amount of data and detail.

Interpretation of the data has been simplified by a sophisticated topographic plotting algorithm that converts the traditional linear waveform tracings into an esophageal pressure topography or Clouse plot (Fig. 34-18). Sphincter characteristics and esophageal motor function are represented by isocontour manometric plots, eliminating the need for the tedious analysis of the increased waveform data that are generated by the 36 sensors.

The test is performed by passing the catheter into the stomach and esophagus to measure contraction pressures and waveform in the esophageal body and the sphincters' resting pressure and response to swallowing. The lubricated catheter is passed through the nostril and into the esophagus. The catheter is advanced until a portion of the sensors are in the stomach. In patients who have a dilated or tortuous esophagus, such as in cases of suspected achalasia or a large paraesophageal hernia, it is recommended that the catheter be passed endoscopically to ensure that it is properly positioned into the stomach and not coiled in the esophagus. The pressure topogram is assessed to ensure that the catheter is completely

traversing the UES and the LES. Unlike with traditional manometry, a HRM study can be performed with 10 swallows without the need to repeatedly move the catheter back and forth for different portions of the exam. The patient is then asked to refrain from swallowing for 30 seconds with quiet breathing, which allows the capture of a landmark frame for assessment of the resting UES and LES. The patient is positioned supine with the head elevated and is asked to swallow 5-mL aliquots of water separated by a minimum of 30 seconds to prevent deglutitive inhibition. A complete manometric study includes the assessment of the structural characteristics of the LES, the degree of LES relaxation, the esophageal body coordination, contraction amplitude and waveform, and the UES function.

Lower Esophageal Sphincter

The resting LES is assessed during the landmark frame (Fig. 34-19). The lower (distal) border of the LES is the point at which the resting pressure rises above the gastric baseline; the upper border is the point at which sphincter pressure reaches the esophageal baseline. The respiratory inversion point is identified when the positive excursions that occur with breathing in the abdominal environment change to negative deflections in the thoracic environment. The respiratory inversion point is the functional division between the abdomen and thorax. The resting pressure of the LES is the pressure above gastric baseline measured during mid-respiration at the respiratory inversion point. The overall length of the sphincter is the distance from the distal border to the proximal border. The abdominal length is the distance from the distal border to the respiratory inversion point and represents the portion of the LES that is subject to fluctuations in intra-abdominal pressure. The measurements for each of these components from each transducer are expressed as an average during the landmark frame, which extends for 30 seconds.

FIGURE 34-18 ■ The distinction between high-resolution manometry (HRM) and esophageal pressure topography (EPT). The HRM catheter consists of 21 to 36 closely spaced pressure sensors. The position of pressure sensors in the esophagus is indicated in the anatomic drawing on the left. In the middle panel, the data from HRM records are displayed as tracings for each pressure sensor, similar to conventional manometry. EPT is illustrated on the right. EPT is distinct from HRM in that it is purely a data analysis method, whereas HRM is a data acquisition method. The Clouse plots (EPT plots) are derived from the data acquired from HRM and are displayed using a color code to describe peristaltic amplitude in a space-time continuum. A technique of interpolating between the recording sensors allows one to obtain a seamless representation of the pressure activity through the entire swallow. Note the tremendously enhanced detail provided by the Clouse plot, especially in the area of the esophagogastric junction. (From Pandolfino JE, Roman S: High-resolution manometry: an atlas of esophageal motility disorders and findings of GERD using esophageal pressure topography. *Thorac Surg Clin* 21(4):465–475, 2011.)

FIGURE 34-19 ■ High-resolution esophageal manometry showing the landmark frame. The upper and lower esophageal sphincters are observed at the top and bottom of the frame, respectively. Resting pressure and length measurements of the sphincters can be determined in this portion of the study while the patient is refraining from any swallowing.

A structurally defective sphincter is identified as one that has low resting pressure or short length. Based on conventional manometry in normal volunteers, the following characteristics have traditionally been used to identify a structurally defective LES: (1) an average LES pressure of less than 6 mm Hg, (2) an average abdominal length of less than 1 cm, and (3) an average overall length of less than 2 cm. Based on normative data, these values are below the 2.5 percentile. A defect in one or even two components of the LES may be compensated by good esophageal body function, but when all three components are defective, excessive esophageal acid exposure is inevitable.

It should be noted that whereas HRM has revolutionized the assessment of the esophageal body as a result of improved resolution of contraction waves, the assessment of the LES has been less than optimal. This is primarily because of the nature of the HRM catheter, which functions as a sleeve manometry catheter and results in circumferential averaging of pressure data. For this reason, length assessment of the LES and UES is believed to be suboptimal compared with that obtained with conventional manometry with a manually pulled through catheter.⁴⁶ It is hoped that the newly developed three-dimensional HRM catheter will allow more precise or detailed evaluation of the LES structure, but clinical experience is necessary to fully evaluate its additive value.

Lower Esophageal Sphincter Relaxation

The LES pressure normally drops to gastric baseline immediately after initiation of a swallow and remains open until the oncoming peristaltic wave reaches the stomach (Fig. 34-20). A characteristic postrelaxation contraction of the LES is subsequently observed as the LES closes with passage of the bolus. Using HRM, relaxation is assessed during a 4-second integrated relaxation

FIGURE 34-20 ■ High-resolution esophageal manometry during a swallow. The initiation of swallowing is reflected by transient relaxation of the upper esophageal sphincter followed by a peristaltic pressure wave progressing down the esophageal body. Note the lower esophageal sphincter (LES) relaxes at the initiation of swallowing. A characteristic peristaltic break is observed in the upper third of the esophageal body at the transition zone between the striated and smooth muscle.

pressure (IRP). This 4-second window is often captured in a noncontiguous manner during the swallow to eliminate the effect of respiratory variation from the crura. A residual pressure of greater than 15 mm Hg is considered elevated and may result in clinically significant outflow resistance of bolus transport through the esophagus.

Esophageal Body Motility

The esophageal body is evaluated by assessing its contraction amplitude, duration, slope, velocity, and morphology (i.e., single, double, or triple peaked) (see Fig. 34-20). A physiologic gap in contraction or proximal peristaltic break typically occurs in the upper one third of the esophagus and corresponds to the transition zone between the striated muscle above and smooth muscle below. Pathologic breaks are those that are longer than 2 cm or if a break occurs in the distal esophagus. HRM has had its greatest improvement in the assessment of esophageal body function. It is important to allow 30 seconds between swallows to prevent deglutitive inhibition of the body, a physiologic dampening or absence of peristalsis with repetitive swallowing.

Further improvement in assessing esophageal body function with HRM has been the use of the distal contractile integral (DCI), which gives a global assessment of esophageal contractile function. This is an integrated summation of the contractile pressures generated between the proximal peristaltic break and the upper border of the LES and is calculated as the product of amplitude (mm Hg) $\times$ duration (seconds) $\times$ length (cm), with normal values ranging from 500 to 4300 (Fig. 34-21). Based on conventional manometry, it was believed that a minimum of distal contraction amplitude of greater than 20 mm Hg at one level 5 cm above the LES was necessary to overcome the resistance of an antireflux procedure. With HRM, it is currently believed that a DCI greater than

FIGURE 34-21 ■ The distal contractile integral (DCI) is measured from the proximal peristaltic break to the top of the lower esophageal sphincter. It provides a more global assessment of esophageal body contractility. (From Pandolfino JE, Roman S: High-resolution manometry: an atlas of esophageal motility disorders and findings of GERD using esophageal pressure topography. *Thorac Surg Clin* 21:465–475, 2011.)

500 mm Hg/sec/cm is necessary to minimize the possibility of postoperative dysphagia; however, clinical validation of this cutoff has not been performed.

Upper Esophageal Sphincter

The position, length, and resting pressure of the UES and its relaxation with swallowing are assessed with a technique similar to that used for the LES. The key features to be assessed are the adequacy of pharyngeal contraction and the timing and extent of UES relaxation. An indirect measure of UES stiffness or loss of compliance is the intrabolus pressure, which appears as a pressure rise or shoulder on the upstroke of the pharyngeal contraction.

High-Resolution Impedance

Even with the addition of high-resolution topography, manometric data often do not exactly correlate with the effective passage of the swallowed bolus. The barium video esophagram has been used to complement this shortcoming of manometry; one drawback, however, is that these tests cannot be performed simultaneously. Not infrequently, a discrepancy may exist between these studies with a normal video esophagram but poor esophageal body manometry characteristics, or vice versa. Currently, the authors are using combined high-resolution manometry with high-resolution impedance to gain additional information on bolus transport.

Ambulatory pH Monitoring

The development of ambulatory pH monitoring was a major advance in the unraveling of the pathophysiology of GERD. All previous tests had relied on the

identification of reflux by a provocative maneuver, which had little relevance to the patient's daily activities. The 24-hour pH monitoring test made it possible to determine if the time of esophageal exposure to gastric juice in a patient during a 24-hour period was greater than what was found in normal subjects.

The 24-hour pH monitoring test is considered by many to be the gold standard for the diagnosis of GERD because it has the highest sensitivity and specificity of all tests currently available. It is indicated in any patient with symptoms suggestive of GERD, unless the symptoms are trivial or permanently abolished by a short course of acid suppression therapy. The need for continued acid suppression should stimulate objective study. A 24-hour pH monitoring study is especially important in patients who are being considered for antireflux surgery. Atypical presentations of GERD are also a common indication; they include such symptoms as noncardiac chest pain (i.e., pain despite a normal cardiac evaluation) and respiratory symptoms such as shortness of breath, cough, nocturnal wheezing, and chronic hoarseness. In such patients, 24-hour pH monitoring allows confirmation of the diagnosis of GERD and can relate the occurrence of the symptoms to an episode of reflux.

To perform the test, a thin catheter containing a pH electrode is passed transnasally into the esophagus and placed 5 cm above the upper border of the LES, a position that has been previously determined by manometry. Different probes are available, but bipolar glass electrodes are preferred for their greater reliability and their elimination of the need for an external reference electrode. The electrode is connected to an external portable digital storage device that is kept at the patient's side, and pH values are continuously recorded at 6-second intervals for 24 hours (i.e., a complete circadian cycle). Precalibration and postcalibration of the system to pH levels of 1 and 7 is important to exclude electrode drift. A gastric "dipstick" maneuver is performed prior to securing the location of the catheter to confirm acid in the stomach and to ensure that the patient does not have atrophic gastritis. The patient is then instructed to carry out normal daily activities but to avoid strenuous exertion. He or she is asked to remain in the upright position while awake during the day, lying down supine only at night while sleeping, and to ingest two meals at the usual time. The diet is standardized only by its absence of food and beverages with a pH value of less than 5.0 and greater than 6.0. The patient notes in a diary the times of meals, retiring for sleep, and rising the following morning as well as the presence and duration of any symptoms. At the authors' institution, patients are also asked to consume a challenge meal consisting of a hamburger, French fries, and a milk shake. It has been found that a refluxogenic meal can often uncover early acid reflux disease that would not ordinarily be detected during a typical 24-hour period.⁴⁷ Figure 34-22 shows typical 24-hour pH tracings from a healthy subject and from a patient with GERD. Medications such as H₂ blockers and prokinetics should be discontinued for 48 hours before the testing begins. Proton pump inhibitors (e.g., omeprazole) should be stopped for 2 weeks before pH monitoring because of their long-lasting action.

FIGURE 34-22 ■ Tracings of 24-hour pH monitoring of the distal esophagus in a healthy subject (*top*) and in a patient with gastroesophageal reflux disease (*bottom*). Physiologic reflux occurs in the normal subject, mainly in the upright position after meals. The patient's record shows an increased number of reflux episodes in both upright and supine positions, some of them with prolonged clearing time.

It is important to emphasize that 24-hour esophageal pH monitoring should not be considered a test for reflux; rather, it is a measurement of the esophageal exposure to gastric juice. The measurement is expressed as the percentage of time that the esophageal pH was below 4 during the 24-hour period. Just measuring the percentage of time that the pH is less than 4, although concise, does not reflect how the exposure has occurred; for example, it may have occurred in a few long or several short reflux episodes. Consequently, two other assessments are necessary: (1) the frequency of the reflux episodes and (2) their duration. For this reason, esophageal exposure to gastric juice is best assessed by the following measurements⁴⁷:

- The cumulative time that the esophageal pH is below 4 expressed as the percentage of the total, upright, and supine monitored times;
- The frequency of reflux episodes, when the pH drops below 4, expressed as the number of episodes per 24 hours;
- The number of episodes during which the pH remained below 4 for longer than 5 minutes per 24 hours; and
- The time in minutes of the longest recorded reflux episode, the longest time the pH consistently remained below 4.

Normal values for these six components of the 24-hour record were derived from 50 asymptomatic control subjects. The upper limits of normal were established at the 95th percentile.⁴⁷ If the values of symptomatic patients are outside of the 95th percentile of normal subjects, they are considered to be abnormal for the component measured. There is a uniformity of normal values for these

six components as reported by centers throughout the world. The normal values for the six components obtained from 50 healthy volunteers are shown in [Table 34-1](#). A composite scoring system has been derived that integrates the different components of the pH record into a single measurement of esophageal acid exposure. This composite score is calculated from the six parameters with use of their standard deviations as weighing factors.⁴⁷

Advances in technology have made pH testing more comfortable for the patient. The development of a catheter-free miniaturized pH electrode has revolutionized the way that standard ambulatory pH testing is performed. The Bravo system (Medtronic, Minneapolis, MN) allows the transnasal or transoral deployment of a small capsule attached to the esophageal mucosa that is capable of transmitting pH data by radiotelemetry to a pager-sized receiver, thus eliminating the need for an unpleasant catheter. It may also provide a more accurate physiologic picture by allowing patients to perform their normal daily activities without the social and behavioral restrictions imposed by the catheter. Another major advantage of the Bravo capsule is the ability to record for prolonged periods, and routine monitoring of 48 hours is now performed with improved diagnostic capabilities.⁴⁸ New normal thresholds have been defined and validated for the 48-hour Bravo pH test, with the normal composite score for the first 24 hours being 14.0, the second 24 hours being 14.0, and the combined 48-hour score being 16.0.⁴⁸

In patients with symptoms of chronic cough, hoarseness, or pulmonary aspiration, placement of an additional pH electrode in the proximal part of the esophagus or pharynx can be helpful.⁴⁹ Such dual probe catheters are

TABLE 34-1 Esophageal Acid Exposure 5 cm above the Upper Border of the LES during 24 Hours of Ambulatory pH Monitoring in 50 Healthy Volunteers

Component	95th Percentile
% Total time pH < 4	4.5%
% Upright time pH < 4	8.4%
% Supine time pH < 4	3.5%

LES, Lower esophageal sphincter.

From Johnson LF, DeMeester TR: Twenty-four-hour pH monitoring of the distal esophagus: a quantitative measure of gastroesophageal reflux. *Am J Gastroenterol* 62:325–332, 1974.

particularly helpful in determining if gastroesophageal reflux events extend proximally, which could give indirect evidence of acid exposure into the pharyngeal area and subsequent irritation. If the accumulated acid exposure in the proximal esophagus is greater than 1% or the number of reflux episodes is more than 24 (particularly if there is a temporal relationship between the reflux episodes and the onset of the symptoms), reflux can be documented and assumed to be the cause of the patient's respiratory symptoms.⁴⁹ A composite score has been developed for proximal pH monitoring, analogous to that developed for the distal probe, with the normal threshold composite score being 16.4.⁴⁹

Additional testing is sometimes necessary if the standard methods of assessing esophageal function fail to yield conclusive results, particularly when investigating the relationship of acid reflux and extraesophageal symptoms. A novel pharyngeal pH system has been developed that allows a pH probe to be positioned directly into the pharynx just below the uvula (Restech pH probe, Respiratory Technology Corp, San Diego, CA).⁵⁰ This probe uses a novel antimony sensor that allows measurement of pH within the humidified air of that environment without drying out and creating artifacts. Early clinical experience with this technique indicates that it is a useful adjunct diagnostic test in patients suspected of having laryngo-pharyngeal reflux.

Testing for reflux that is nonacidic or weakly acidic can be gained by multichannel intraluminal esophageal impedance monitoring. This type of measurement determines the resistance to the flow of current through a given medium (impedance). The impedance to current changes as the composition of the medium in which the current is traveling changes (i.e., air, liquids, or solids). Coupled with a pH probe, it can differentiate acid reflux from nonacid reflux, which may be particularly important in patients who remain symptomatic on acid suppression therapy.

Lastly, the assessment of gastric function can be important in many patients with esophageal symptoms. Disorders of gastric emptying frequently can contribute to, or be confused with, esophageal disease, especially GERD. Nuclear medicine radioisotope with solid food

matter such as scrambled eggs has been used for this purpose and is indicated in any patient being evaluated for GERD who also has a history of nausea, early satiety, and vomiting. Such information may be invaluable to prevent performing an antireflux operation in the setting of gastroparesis.

EMBRYOLOGY

At approximately the 18th or 19th day of fetal life, the notochord, the anlage of the vertebral column, starts to form, first in close association with endodermal cells and then separating from them. The foregut develops from the endodermal cells as they are separating from the notochord. At approximately 3 weeks of embryonic development, the tracheal primordium appears as a ventral diverticulum in the cephalad portion of the foregut. Over the next few weeks, growth and elongation of the diverticulum and the foregut along the tracheoesophageal groove contribute to the separation of the esophagus and the trachea, which is complete by approximately 5 to 6 weeks of fetal life. During the seventh and eighth weeks, the esophageal epithelium proliferates and fills the lumen almost completely. Vacuoles appear in the lumen and eventually coalesce to recanalize it by the 10th week.¹

The major anomalies of the esophagus are a result of some aberration in the orderly development of the organ. Failure of separation of the trachea and esophagus may result in esophageal atresia (EA) with or without a tracheoesophageal fistula (TEF) and laryngotracheoesophageal clefts. Tracheobronchial elements including cartilage can be left behind in the distal esophagus and cause congenital esophageal stenosis. Failure of recanalization of the esophageal lumen may contribute to the pathogenesis

of EA and esophageal webs. Intramural esophageal duplication cysts may result from failure of the esophageal vacuoles to completely coalesce and disappear. Aberrations in the orderly separation of endodermal cells and the notochord may explain the formation of duplication cysts in the posterior mediastinum and vertebral defects associated with EA.

An Adriamycin-induced murine model of EA was described.² Using this model, investigators are studying the role that patterning genes and proteins like Sonic hedgehog (*Shh*) might play in the morphogenesis of EA.^{3,4} Using the same rat model as well as neonates with EA/TEF, Spilde and coworkers have studied the molecular expression of foregut-patterning genes to shed a light on the origin of the TEF. The distal esophagus seems to arise as a diverticulum of the trachea, which elongates and joins the stomach, rather than from the foregut itself.^{2,5,6} They speculate that this might explain the well-known poor motility of the esophagus.

ESOPHAGEAL ATRESIA

Historical Aspects

The historical background relevant to EA is thoroughly reviewed by Harmon and Coran.⁷ Durston in 1670 and Gibson in 1697 described the first cases of EA. It took

approximately 250 years before the first cases of survivors were reported by Leven and Ladd independently in 1939. Both were able to achieve success by performing a series of operations, including gastrostomy, ligation of fistula, marsupialization of the upper pouch, and final reconstruction with an antethoracic skin tube. The early attempts at primary repair were all unsuccessful. It was not until 1941 that Haight reported the first survivor of a primary repair. In the decade that followed, it became evident that the mortality in infants of lower birth weights, those with severe associated anomalies, and those critically ill from aspiration pneumonia was very high.⁸⁻¹⁰ There followed a shift toward staging the operation for sick babies, with a gastrostomy, followed by division of the TEF and the esophageal reconstruction performed as a third stage.⁸⁻¹⁰ In 1962, Waterston proposed a classification based on birth weight, presence of pneumonia and associated anomalies.⁹ The 1970s and 1980 witnessed major advances in respiratory, neonatal, anesthetic, and surgical care, as well as introduction of more effective antibiotics. These advances included endotracheal intubation, which made it easier to prevent aspiration from the esophageal pouch and to deal with its sequelae. As a result, multiple groups started recommending either direct primary anastomosis (anastomosis shortly after birth) or delayed primary anastomosis (anastomosis delayed for the treatment of other life-threatening anomalies or stabilization of the patient) regardless of the patient's weight but based on physiologic criteria.¹¹⁻¹⁹ The end of the 20th century ushered in the application of thoracoscopy to the repair of EA/TEF and other congenital anomalies of the esophagus.²⁰⁻²⁷

Epidemiology

The average rate of EA is reported to be approximately 2.4 per 10,000 births.²⁸ There is no significant described sex predilection. Other congenital anomalies occur in patients with EA frequently, ranging from 30% to 76%.²⁹⁻³³ This might be because the malformation in EA occurs early in the first trimester when there is active organogenesis. As a result, the developmental cause of EA/TEF might also affect other organ systems at the same time. The number of associated anomalies occurring in each patient increases with decreasing birth weight.^{29,34,35} With the improvement in anesthetic, respiratory, and neonatal techniques over the past few decades, the associated anomalies are now the major contributor to mortality in patients with EA.³¹ The most common associated anomaly is congenital heart disease, present in some form in approximately one fifth of patients.^{29,33-37}

Approximately 20% of patients will have some combination of the constellation of anomalies referred to as VATER or VACTERL association: *v*ertebral, *a*norectal, *c*ardiac, *t*racheo*e*sophageal, *r*enal or *r*adial, and *l*imb anomalies.^{36,37}

Babies born with EA often have low birth weight and are premature.^{35,38} In one study, 90% of the patients with EA were below the 50th percentile for gestational age, and 40% were below the 10th percentile or small for gestational age (SGA).³⁹ The growth retardation might be secondary to decreased absorption of the amniotic fluid protein or from a mechanical factor.³⁹ Severe intra-uterine growth retardation increases the mortality rate of the SGA neonate by 5 to 20 times that of appropriate-for-gestational age neonates of the same gestational age.⁴⁰

Anatomy

There are five types of EA with or without TEF. The types of EA are numbered differently depending on the classification scheme, so it is preferable to describe the actual anomaly rather than assign it a number or a letter: EA with distal TEF, EA without TEF, EA with proximal TEF, EA with proximal and distal fistula, and isolated TEF (H-type TEF) (Fig. 35-1). The distribution of the different types in large series has been relatively uniform across decades and countries with the most common being EA with distal TEF (Table 35-1).^{11,29,41-43} The fistula is usually small and most of the time arises from the midline of the membranous portion of the trachea just above the bifurcation; however, significant variations exist.

Presentation

A significant number of cases of EA are now suspected on prenatal ultrasonography, with polyhydramnios, absent or small stomach bubble, and visualization of an

TABLE 35-1 Distribution of Types of Esophageal Atresia

Type of Anomaly	Number	Percentage
EA with distal TEF	1024	87.1
EA	82	7.0
H-type TEF	37	3.1
EA with proximal TEF	11	0.9
EA with double TEF	22	1.9

esophageal pouch in the neck being the most prominent features.^{44,45} Suspecting the diagnosis prenatally is invaluable in preparing the family. Prenatal counseling with a pediatric surgeon and a neonatologist and planning for appropriate delivery arrangements are extremely helpful. Postnatally, most patients with EA are diagnosed in the first few hours after birth. Choking with feeding, regurgitation of saliva and feeds, respiratory distress from aspiration of saliva or gastric contents through the TEF are the most common signs and symptoms. Inability to pass a feeding tube confirms the diagnosis.

Patients with isolated TEF (H-type TEF) may not be diagnosed until later in life. Recurrent episodes of aspiration pneumonia and choking and coughing with feedings should raise the suspicion. Contrast esophagram and rigid bronchoscopy are complementary in making the diagnosis, which is often very difficult to make.⁴⁶

Patients with isolated EA often have a scaphoid abdomen because of the absence of gas in the intestines. If EA is suspected, one should always look for other physical signs of the VATER association: anorectal malformations, limb anomalies, and vertebral defects (Fig. 35-2).

Workup

A chest radiograph showing a curved catheter in the proximal esophageal pouch is often all that is required to make the diagnosis (Fig. 35-3). In patients with isolated EA, the radiograph reveals absence of intestinal air (Fig. 35-4). If still in doubt, a small amount of air injected into the pouch accentuates it on a plain radiograph and confirms the presence of EA (Fig. 35-5). The use of barium to look for an upper pouch fistula should be discouraged because it may potentially lead to aspiration. Upper pouch fistulae are rare and are usually found at the time of repair by either bronchoscopy or a careful dissection of the proximal pouch. An esophagram performed via a catheter being pulled up along the esophagus while the patient is prone is invaluable in making the diagnosis of H-type fistula (Fig. 35-6).

FIGURE 35-2 ■ Radial aplasia, one component of the VATER association.

An echocardiogram, renal ultrasound, and vertebral films are often performed to rule out major cardiac, renal, and vertebral anomalies as part of the VATER association. The echocardiogram is also helpful in determining the location of the aortic arch and of any aberrant central vessels, which might alter the surgical approach. Recently,

the need for a preoperative echocardiogram in asymptomatic patients has been questioned.⁴⁷

Initial Management

Patients born with EA are at risk for aspiration of saliva or gastric contents into the tracheobronchial tree. A

Replogle-type soft sump suction catheter with the holes close to the tip should be placed in the upper pouch and put on continuous suction. In the presence of a TEF, the patient should be placed in the reverse Trendelenburg position with the head up to minimize reflux of gastric contents into the trachea. Having the patient prone might also help to keep the gastroesophageal junction at a less dependent position and decrease gastric reflux. With isolated EA, the Trendelenburg position facilitates the passive drainage of the hypopharynx and complements the active suction of the catheter. Even with a drainage catheter in place, frequent suctioning of the hypopharynx helps in decreasing the risk of aspiration. If there is any evidence of aspiration pneumonitis on a radiograph, broad-spectrum antibiotics should be started.

If possible, positive-pressure ventilation should be avoided in a patient with a TEF to minimize shunting through the TEF and abdominal distention. Because most fistulae are located just proximal to the carina, the tip of the tube should be kept high in the trachea to prevent the tip of the tube from becoming lodged in the TEF. Sometimes, the TEF is significant enough that adequate ventilation cannot be maintained, especially in the presence of respiratory distress syndrome (RDS), in premature patients, with its attendant high intraparenchymal pressures. In these cases, emergent ligation of the TEF or division of the esophagus might be warranted.^{48,49} A more difficult way to control the TEF emergently is obliteration of the TEF with a Fogarty balloon introduced via bronchoscopy.⁵⁰ A hazardous situation can occur when a patient with significant steal through a TEF also has a very high intestinal obstruction, such as duodenal atresia. The massive gastric distention exacerbates the respiratory compromise and could lead to perforation of the stomach. Emergent gastric decompression has to be performed, sometimes at the bedside with a needle.

The timing of surgery is of particular interest. The key issues affecting the timing include severity of the infant's condition, associated abnormalities, and birth weight. The Spitz classification identified low birth weight (<1500 g) and major congenital heart disease as two major risk factors associated with EA.⁵¹ This system stratifies patients into groups. Survival was estimated at 97% for group I (weight > 1500 g with no major congenital cardiac defect), 59% for group II (birth weight < 1500 g or major congenital cardiac defect), and 22% for group III (birth weight < 1500 g and major congenital cardiac defect). In 2006, Lopez validated the original Spitz classification in a series of 188 neonates.⁵² Weight-based classification systems such as the Spitz and Waterston classifications have traditionally been used to assess prognostic outcomes with surgical intervention. However, others have not found weight to be an independent predictor of survival.^{53,54}

Several groups investigated the issue of operating on extremely low-birth-weight (ELBW, weight < 1000g) infants and very low-birth-weight (VLBW, weight < 1500 g) infants and the ideal surgical management of these patients is still controversial. In 2006, Seitz and colleagues published their data of four children who underwent open primary repair of EA/TEF whose weight

ranged from 780 to 1120 grams.⁵⁵ Their postoperative complications included one patient with anastomotic leak and a separate patient with esophageal stenosis requiring dilation. They concluded that a one-stage approach is a good option in ELBW children. In 2009, Petrosyan and colleagues published a retrospective review of 25 VLBW infants with EA/TEF who underwent open operative repair between the years of 1987 and 2008.⁵⁶ The researchers divided these patients into two groups: 16 of these patients underwent primary repair and 9 underwent staged repair. There was no difference in patient characteristics, including weight or mean gestational age. However, there was a significantly higher rate of anastomotic leak (50% versus 0%), strictures (81% versus 33%), and sepsis/pneumonia (81% versus 66%) in the primary repair versus staged repair groups, respectively. They concluded that there are increased risks of postoperative complications in premature VLBW infants with EA/TEF and recommended a staged surgical approach in these patients, which is consistent with the series of Chahine and Ricketts.³⁵

Operative Principles

Rigid bronchoscopy is helpful at the beginning of the procedure to identify the exact location of the TEF, recognize rare variants like double fistulae or H-type fistula and laryngotracheoesophageal clefts, identify the presence of tracheomalacia, and help in placement of the endotracheal tube to avoid dislodgement into the TEF (Fig. 35-7).⁵⁷⁻⁵⁹

Primary repair of EA with division of the TEF and end-to-end anastomosis is the ideal goal (Fig. 35-8). The standard approach is a right posterolateral thoracotomy. If the patient has a right-sided aortic arch, it might be easier to approach the esophagus from the left thorax.

FIGURE 35-7 ■ Bronchoscopic appearance of a tracheoesophageal fistula (arrow) in the membranous portion of the trachea proximal to the carina.

Having the patient tilted forward in the near prone position facilitates access to the posterior mediastinum. To minimize some of the complications reported with thoracotomy in neonates, namely winged scapula and scoliosis, an axillary skin crease thoracotomy (reported by Bianchi⁶⁰ and used with good results⁶¹) may be considered. Traditionally, an extrapleural approach has been advocated to decrease the risk of empyema if an esophageal leak occurs. With the introduction of more powerful antibiotics in the 1970s and 1980s, the importance of a retropleural approach with the potential increase in operative time has been questioned.^{41,62}

The posterior mediastinum is exposed by dividing the parietal pleura. The azygous vein is divided to allow access to the TEF, which is usually located behind it. The fistula is circumferentially controlled and occluded. The fistula is divided leaving approximately 1 mm of esophageal tissue on the tracheal side to avoid narrowing the tracheal lumen. Leaving more than a minimal amount of esophageal rim might create a pouch, which could accumulate secretions and cause repeated aspirations. The tracheal defect is closed in an airtight manner, usually with an absorbable monofilament suture.

Gentle pressure by the anesthesiologist on the pouch catheter helps to identify the upper pouch, which is usually high in the thoracic inlet. A transmural suture placed through the fistula and incorporating the catheter makes the manipulation of the upper esophagus less traumatic. The upper pouch and the trachea are intimately juxtaposed, often sharing a common wall. The dissection between the esophageal pouch and the trachea is delicate. Extreme caution should be applied to avoiding injury to both vagus and recurrent laryngeal nerves. The pouch is mobilized as high as possible to minimize the tension of the anastomosis. The blood supply of the upper esophagus is intramural, allowing for minimal ischemia even after extensive mobilization. In contradistinction, the lower esophagus is supplied by segmental branches from the aorta; therefore, its mobilization should be minimized to prevent ischemia. The ends of the esophagus are trimmed, and an end-to-end anastomosis is built in a single-layer fashion with fine monofilament absorbable sutures. The knots are tied extraluminally if possible. It is crucial to identify the mucosa of both the upper and the lower esophagus and incorporate it in the sutures. If there is significant tension, it is helpful to leave the sutures untied and approximate all at the same time because the knots are tied to take some of the tension off. The esophageal and tracheal suture lines must be separated to avoid fistula formation. This is usually accomplished by the interposition of a pleural flap, but sometimes a pericardial flap is required. The routine use of transanastomotic feeding tubes remains controversial.⁷ Before constructing the anastomosis, the surgeon needs to rule out congenital esophageal stenosis by passing a tube through the distal esophagus into the stomach.⁶³ At the completion of the procedure, a small chest tube is placed and secured to the endothoracic fascia away from the anastomosis. At approximately 5 or 7 days postoperatively, a contrast study is obtained to assess the anastomosis. The disparity in size between the distended proximal pouch and the small distal esophagus gives the

FIGURE 35-8 ■ Construction of the anastomosis in a patient with esophageal atresia and tracheoesophageal fistula. End sutures are placed to draw the ends of the esophageal segments together. A single row of simple sutures completes the front-presenting portions of the anastomosis, with the knots tied on the outside. One of the corner sutures is passed behind the esophagus, which is then rotated 180 degrees. The anastomosis is completed with simple sutures in the presenting posterior surface, which has been rotated into view. It is essential that the sutures are full thickness because the mucosa has a tendency to retract.

appearance of a narrowing, but usually prompt emptying of contrast attests to the wide patency of the anastomosis (Fig. 35-9A). With time, the size discrepancy becomes less pronounced (see Fig. 35-9B). If there is no leak, the chest tube is removed and feedings are started. Because of the frequent occurrence of gastroesophageal reflux (GER) and the deleterious effects acid can have on a fresh anastomosis, serious consideration should be made to keep the patient on acid suppressing and promotility drugs until the anastomosis is well healed.

Repair of EA in patients with significant gaps between the two ends of the esophagus can be challenging. The magnitude of the challenge is reflected in the number of innovative techniques described to save the native esophagus. Rehbein and Schweder proposed approximating the two ends as much as possible and waiting for a fistula to develop around the sutures then dilating that fistula.⁶⁴ Staging the operation with initial ligation of the TEF and delayed primary anastomosis has been advocated.⁶⁵ The growth of the esophagus can be spontaneous or active with serial bougienage of the upper pouch. Delayed primary anastomosis is certainly a safe and effective strategy in patients with very low birth weight in whom the tissues are friable or in patients who are unstable.^{13,35} Livaditis and Eklof described performing a circular myotomy on the upper esophagus to gain length.¹⁹ This has been used with good results by multiple groups.⁶⁶⁻⁶⁸ Delayed ballooning and diverticulum formation are two described long-term complications of circular myotomy.^{69,70} A second circular myotomy can be added via a cervical incision if more length is still needed. Kimura and colleagues advocate elongating the esophagus by performing a series of cervical esophagostomies with gradual elongation.⁷¹ Foker et al proposed the application of tension on the two ends through sutures brought out of the skin and tightened sequentially.⁷² Elongating the distal esophagus by performing a Collis-Nissen

fundoplication at the time of repair of EA has been described.⁷³ Schärli advocates division of the lesser curvature of the stomach to elongate it and partial gastric transfer to gain as much as 6 cm in length in the treatment of long-gap atresia and pure EA.⁷⁴ Tubularization of the upper pouch after creation of a U-shaped flap is an attractive technique described by Bar-Maor et al.⁷⁵

The repair of pure EA without a TEF is even more challenging. The distal esophagus is usually very short and the gap significant. All of the previously described techniques can be tried in this situation. Traditionally, the most common approaches were delayed primary anastomosis or esophageal replacement.⁷⁶ Colonic interposition, jejunal interposition, creation of a gastric tube, and gastric transposition are well-established techniques for esophageal replacement in children.⁷⁷⁻⁸⁰ More recently, the Foker technique of esophageal elongation with traction and delayed primary anastomosis has become a popular approach in the surgical treatment of these difficult patients. In 2013, Nasr and Langer performed a systematic review and cumulative meta-analysis that included articles describing the Foker technique or delayed primary anastomosis in patients with long gap EA.⁸¹ They compared 71 patients undergoing the Foker technique to 451 children undergoing delayed primary anastomosis with a primary outcome of postoperative complications and secondary outcome of time to definitive anastomosis. Their data showed a significantly lower rate of postoperative complications in the Foker group, including GER, anastomotic leak rate, and postoperative stricture rate. Additionally, there was a significant decreased time to definitive anastomosis between the Foker group and delayed anastomosis group at 14 ± 8.2 days versus 83 ± 62 days, respectively. They concluded that the use of mechanical traction is at least as effective as delayed primary anastomosis in this patient population.

FIGURE 35-9 ■ **A**, Postoperative esophagram at 1 week revealing a patent anastomosis and a size discrepancy between the proximal and distal esophagus. **B**, Esophagram at 2 months postoperatively showing a decrease in the size discrepancy.

The approach to an H-type fistula is usually through a right cervical incision because most of these fistulae are in the neck. Direct division of the fistula and repair of the esophagus and tracheal components are the goal (Fig. 35-10). Placing a wire through the fistula via bronchoscopy and retrieving it from the mouth aid in the identification of the fistula and offer the opportunity to apply cephalad traction on the fistula to bring it up from the thorax if it is more distal than usual.⁸²

In 1999, Lobe and colleagues performed the first thoracoscopic repair of isolated EA.²¹ Since then, multiple groups have reported the successful thoracoscopic repair of EA with TEF (Fig. 35-11).^{24,25,83-85} This method of repair has become more widely practiced. In 2005, Holcomb et al performed a multi-institutional retrospective review of 104 newborns with EA/TEF undergoing thoracoscopic repair.⁸⁶ Their results demonstrated advantages such as superior visualization of the anatomy within the thoracic cage and decreased musculoskeletal deformities (i.e., winged scapula, thoracic wall asymmetry, serratus anterior muscle atrophy, thoracic scoliosis). In comparison to open repair, operative time was slightly

shorter at approximately 2 hours and time on the ventilator was slightly longer at 3.5 days. Time at discharge (18 days) was comparable between the two techniques. However, this is a phase I study and does not answer the question if the thoracoscopic technique is superior to the open approach.

Several articles have been published since Holcomb's publication comparing the minimally invasive and open approaches. However, none of these comparisons involved prospective randomized trials. In 2012, Burruto and colleagues published a meta-analysis of several retrospective reviews ultimately comparing 69 thoracoscopic to 97 thoracotomy approaches to EA/TEF.⁸⁷ Their primary endpoints were intraoperative and postoperative complications. They found no statistically significant difference in intraoperative complications in either group. Additionally, they did not find a difference in postoperative complications, including leak rate and stricture rate, between these groups. They concluded that the outcome of thoracoscopic technique is no different from that of the open technique but that a randomized controlled trial was necessary to determine which procedure is superior.

FIGURE 35-10 ■ Repair of H-type fistula. An incision is made in the neck. The sternocleidomastoid is retracted or severed. The fistula is divided flush with the esophagus to ensure closure of the trachea without narrowing the lumen.

Complications and Long-Term Effects

Complications of EA repair can be thought of as short term (leak, stricture) and long term (tracheomalacia, GER, nutritional, recurrent fistula, foreign body impaction).

Most large series report the rate of anastomotic leak to be between 15% and 20%.^{36,41,88} Most leaks are small and can be managed nonoperatively with broad-spectrum

antibiotics and thoracic drainage. Very rarely, suture repair or cervical diversion is required for a major leak.

The rate of esophageal stricture following repair is variable, ranging from 4% to approximately 50%.^{36,41,88} The wide range probably reflects the variability in the criteria for defining the stenosis (whether it requires dilations, the number of dilations, and the need for resection). Singh and Shun have proposed to spatulate the distal esophagus, creating a wider anastomosis, as a way

to decrease the rate of stricture formation.⁸⁹ Symptoms include choking, apnea, near-death spells, and food impaction. Most strictures are adequately treated with dilations. Strictures that are refractory to dilations should prompt a diligent search for, and control of, GER, often with a fundoplication. Recalcitrant strictures can also be secondary to the occurrence of ectopic tissues, tumors or tracheobronchial remnants near the anastomosis.^{63,90,91} The standard approach to refractory strictures has been resection and reanastomosis. Recently, the application of interventional radiological techniques has allowed the recanalization of impassable strictures that could not be dilated using standard techniques.^{92,93}

GER is a major concern in patients with EA, occurring in as many as 54% of patients.^{36,88} It is a significant contributor to the rate of occurrence of leaks and strictures as well as to respiratory complications, including aspiration pneumonia and cyanotic, near-death spells.⁸⁸ Most patients with significant GER eventually require a fundoplication to control their symptoms. The short-term morbidity of fundoplication in patients with EA is higher than in the general population, perhaps because of the dysmotility of the distal esophagus. A partial fundoplication, such as the Toupet 270-degree wrap, could be considered in patients with severe dysmotility or small stomachs.

With the significantly increased rate of GER in this patient population, there is a concern for metaplasia of the esophageal mucosa and eventual development of esophageal cancer. Sistonen and colleagues studied 502 patients who had surgery for EA at the University of Helsinki between the years 1949 and 1978. A chart review of these patients was performed with a primary focus of the development of cancer until the patient's death or December 2004, whichever came first.^{94,95} None of these patients developed esophageal cancer. They found that the statistical risk of EA patients' developing esophageal cancer postoperatively is less than 500-fold that of the general population. Additionally, the overall cancer incidence was similar to that of the general population. This group did, however, recommend long-term endoscopic surveillance. Since then, several authors have published case reports about adult patients with repaired EA/TEF and GER developing esophageal cancer squamous cell cancer or adenocarcinoma.⁹⁶ In 2010, Burjonrappa et al published an article describing endoscopic results of 51 patients who previously underwent EA/TEF correction.⁹⁷ Endoscopies with biopsies were performed every 3 years beginning at the age of 3. The authors reported that 15% of patients developed metaplasia (gastric metaplasia or Barrett esophagus) with an average lag time of 10 years to develop metaplasia after the initial operation. In 2013 Rintala and Pakarinen updated their recommendation for a surveillance protocol with the initial endoscopy and pH measurement being performed at 1 year of age and follow-up endoscopies continued until 15 years of age.⁹⁸ At that time, patients undergo surveillance endoscopies at 15, 30, 40, 50 and 60 years of age. However, these intervals are shortened to every 5 years if pathologic findings such as erosive esophagitis, esophageal stricture requiring dilation, or columnar metaplasia are noted.

Recurrent TEF occurs in as many as 10% of the patients following EA repair.^{36,41,88,99} Symptoms include coughing, gagging, cyanotic and apneic spells, and recurrent respiratory infections. The diagnosis is difficult to make and relies heavily on contrast studies. Most will require a repeat resection, but a few reports of bronchoscopic obliteration with fibrin glue, laser, or tissue adhesives have been published.¹⁰⁰⁻¹⁰⁴

Tracheomalacia is common in patients with EA and is thought to be secondary to the prolonged compression of the developing trachea by the enlarged esophageal pouch. Patients with EA and severe tracheomalacia often have a characteristic barking cough. Severe symptoms include stridor, choking, apnea, and near-death spells. The diagnosis is confirmed by bronchoscopy performed while the patient is spontaneously breathing and more recently by cinecomputed tomography and magnetic resonance imaging.^{105,106} Symptomatic patients usually benefit from aortosternotomy. Sutures are placed in the adventitia of the aorta and fixed anteriorly to the sternum, therefore suspending the trachea and increasing its diameter. The improvement in diameter is monitored bronchoscopically (Fig. 35-12). This can be accomplished via a left thoracotomy, an anterior thoracotomy, or thoracoscopically.¹⁰⁵⁻¹⁰⁷

Andrassy et al have studied the long-term nutritional status of patients with EA.¹⁰⁸ They found that even though the patients suffered from malnutrition in the first few years after repair, they seem to "catch up" in the later years, especially after the age of 13 years.

Foreign body impaction in the esophagus after EA repair occurs in at least 13% of patients.¹⁰⁹ Often esophagoscopy is needed to clear the esophagus, evaluate for a stricture, and potentially dilate the esophagus. No specific predisposing factors were identified, but the incidence of food impaction decreases after age 5 years.

With the increase in experience with repairing EA, more studies have surfaced discussing the long-term effects of EA repair.^{98,110-115} These studies show an increase in restrictive ventilator defects, bronchial hyper-responsiveness, and asthma, and a 13-fold increase in scoliosis thought to be secondary to thoracotomy-induced rib fusion. Several studies have investigated the quality of life in adults who have undergone EA repair. In 2005, Deurloo et al reported on these quality-of-life issues in 97 patients 16 years and older who had undergone EA repair.¹¹⁶ A questionnaire was sent that included questions from the Gastrointestinal Quality of Life Index, the Illness Cognition Questionnaire, and three open-ended questions. The results to the open-ended questions included 8% who responded in the affirmative to a question asking if there were things that the patient would like to do but could not do because of their EA repair. Limitations that study participants mentioned included inability to play certain sports, inability to lift heavy objects, and dysphagia. Of the participants, 33% answered yes to the question that asked if there are negative consequences of EA; gastrointestinal symptoms were the most common responses. Fourteen percent of patients stated they have positive experiences of EA in their daily life, and 50% of these responders stated they were grateful to be alive. In 2008, Deurloo et al updated their

FIGURE 35-12 ■ **A**, Bronchoscopic appearance of tracheomalacia in a patient with esophageal atresia with tracheoesophageal fistula. Note that the anterior and posterior walls of the trachea are almost touching. **B**, Bronchoscopic appearance of the same patient after aortosternotomy. The anterior wall is now stented open by the suspension of the aorta. (Courtesy Dr. D. Powell, Children's National Medical Center.)

results on the long-term effects of GER, esophageal function, and quality of life in 25 patients older than age 18 after EA repair.¹¹⁷ Manometry, pH measurement, and patient's subjective feeling of dysphagia or heartburn were used to evaluate esophageal function. The study found that 70% of patients met manometric criteria for "ineffective esophageal motility." In this study, 20% of patients showed minor or pathologic reflux based on pH measurements. Interestingly, when these symptoms are compared to their effect on quality of life, dysphagia had a negative effect on quality of life but GER did not.

ESOPHAGEAL DUPLICATIONS

Anatomy and Embryology

The nomenclature of esophageal duplications is confusing. They have been referred to as *enterogenous cysts*, *esophageal duplication cysts*, *neuroenteric cysts*, and *gastrocystomas*, among other terms. In addition, there has been some confusion about bronchogenic cysts when they occur in the mediastinum between the esophagus and the trachea. Because the foregut and the notochord originate in direct continuity to each other and because both trachea and esophagus arise from the primitive foregut, it is helpful to view all these cysts as part of a continuum of foregut duplication cysts.¹¹⁸ The duplications can be lined by alimentary or tracheobronchial mucosa, regardless of where they are located. Approximately 50% of the cysts will contain ectopic gastric mucosa. They can be located in the posterior mediastinum or between the trachea and the esophagus. Cysts located in the posterior mediastinum are often associated with vertebral defects. Intramural duplications probably originate from a failure of vacuolization of the esophageal lumen.¹

Most esophageal duplications do not communicate with the lumen, but they can be tubular with one or more

openings into the lumen. They can be localized to the chest or extend into the abdomen with extensive thoracoabdominal components. Most are located in the distal esophagus, but they can occur anywhere along the length of the esophagus.^{119,120}

Incidence

Esophageal duplications are rare, with an incidence of 1 in 8200.¹¹⁹ Only 10% to 22% of alimentary duplications are esophageal.¹²⁰

Presentation

Approximately one third of patients with esophageal duplications are asymptomatic. Symptomatic patients have a variety of respiratory and intestinal symptoms: dyspnea, wheezing, recurrent infections and pneumonias, dysphagia, anorexia, and bleeding if they have ectopic gastric mucosa.¹¹⁸ If the cyst has a fistula to the spinal canal, meningitis can be the presenting symptom.

Diagnosis

Plain chest radiographs often show a mediastinal mass and aid in the detection of any associated vertebral anomalies. A CT scan will delineate the mass further and allow an exact anatomic localization. If there are any vertebral anomalies, MRI is helpful to rule out intraspinal pathology. Contrast esophagram can show extrinsic or intrinsic compression.

Treatment

Complete resection is the preferred method of treatment, traditionally via a thoracotomy or, more recently, via thoracoscopy.^{20,22,23,26,121} Marsupialization and simple aspiration have a high recurrence rate. If the cyst shares a

common wall with either the tracheobronchial tree or the esophagus, part of the wall can be left behind, but the mucosa has to be stripped to prevent recurrence. Intramural cysts are enucleated without violating the esophageal lumen. A bougie inserted into the esophagus might make the dissection easier. Posterior mediastinal cysts are usually easily excised unless they have an intraspinal component. Cysts located between the esophagus and the trachea can be challenging to remove because of the close association with the trachea. Long tubular thoracoabdominal duplications might require a combined thoracoabdominal approach.

CONGENITAL ESOPHAGEAL STENOSIS

Congenital esophageal stenosis (CES) is a rare anomaly.

Anatomy

Three types of CES have been described: fibromuscular, membranous, and those secondary to tracheobronchial remnants. The latter two are usually refractory to dilations and require surgical relief. These lesions can coexist with EA and should be ruled out at the time of EA repair by inserting a catheter into the distal esophagus.⁶³

Presentation

Patients with CES usually display progressive feeding intolerance and regurgitation. Often the symptoms do not manifest themselves until the patient starts to eat solid foods.

Diagnosis

An esophagram is frequently diagnostic, showing the tapered narrowing in the distal esophagus similar to achalasia. Endoscopic ultrasonography has been used to differentiate stenosis secondary to tracheobronchial remnants from those associated with fibromuscular hyperplasia.^{122,123}

Treatment

Stenosis caused by tracheobronchial remnants and intraluminal membranes do not respond to dilation and require resection with end-to-end anastomosis. One of the complications is esophageal shortening and GER. Nihoul-Fékété et al have recommended the addition of a Nissen fundoplication to the management of distal esophageal stenosis to prevent this complication.¹²⁴ The combined Collis gastropasty and Nissen fundoplication has been proposed to prevent both the shortening and the reflux.¹²⁵

LARYNGOTRACHEOESOPHAGEAL CLEFT

Laryngotracheoesophageal cleft (LTEC) is a rare anomaly arising from the failure of orderly separation of the trachea and esophagus.

Anatomy

There are four subtypes of LTEC¹²⁶:

- Type I: cleft present to, but not below, the vocal cords
- Type II: cleft extends into, but not through, the posterior cricoid cartilage
- Type III: cleft extends through the cricoid cartilage
- Type IV: cleft extends to the trachea

Presentation

LTEC has a wide spectrum of presenting symptoms. Patients with types I to III can have subtle symptoms: chronic cough, wheezing, repeated chest infections. Patients with type IV often have severe symptoms similar to those of patients with TEF: choking with feeding, severe aspiration pneumonia, and respiratory distress.

Diagnosis

Rigid bronchoscopy and esophagoscopy are essential to making the diagnosis. Other associated anomalies, including TEF, GER, congenital heart disease, and cleft lip and palate, should be sought.

Treatment

Observation of asymptomatic patients with type I clefts is often warranted. If they are symptomatic, they could be repaired endoscopically or open. Types II to IV clefts need to be repaired. The lateral pharyngotomy approach has been abandoned because of the high risk of recurrent laryngeal nerve injury and poor access to longer defects. The standard method is a transtracheal approach splitting the airway and trachea in the midline to expose the LTEC, which is then repaired. Long type IV clefts can be challenging to repair and might require cardiopulmonary bypass or extracorporeal membrane oxygenation. A multidisciplinary collaboration between pediatric surgeons, otorhinolaryngologists, and cardiac surgeons is often required.

If GER is significant, aggressive therapy with fundoplication enhances the chances of success of LTEC repair.

CONCLUSION

The esophagus actively transports solids and liquids from the pharynx to the stomach. It has no digestive, absorptive, metabolic, or endocrine functions. A muscular tube subtended by two sphincters performs this rudimentary transfer task. Despite simplicity in esophageal function and form, surgical treatment of benign esophageal disorders is challenging. Few options are available to repair damaged sphincters; disorders of the esophageal body are rarely amenable to surgical correction. Often, progressive disease and/or failed surgical therapy result in a nonreparable esophagus. The only treatment option is resection and replacement. Successful surgical therapy requires a sound understanding of esophageal anatomy, physiology, investigative techniques, and disease processes.

THE ESOPHAGUS AND ITS SURROUNDINGS

Esophageal Wall

The esophagus is lined with stratified, nonkeratinizing squamous epithelium (Fig. 36-1), isolated from the remainder of the esophageal wall by a basement membrane. Immediately beneath the basement membrane is the lamina propria, a thin layer of loose connective tissue with a complex of collagen and elastic fibers. It contains a network of endothelium-lined channels, both capillaries and lymphatics. The muscularis mucosae supports the lamina propria and is composed of a longitudinal layer of

FIGURE 36-1 ■ Esophageal wall and its unique lymphatic drainage. (The Cleveland Clinic Center for Medical Art and Photography © 2009. All rights reserved.)

smooth muscle. This continuous muscle layer pleats the inner layers of the esophagus into a series of folds that disappear with distention. The epithelium, lamina propria, and muscularis mucosae comprise the esophageal mucosa.

The submucosa is composed of connective tissue that contains a network of blood vessels and lymphatics. Elastic fibers and collagen combine to make this the strongest esophageal layer. Submucosal glands are mixed types, producing a combination of serous and mucous secretions. These submucosal glands are unique to the esophagus and allow differentiation of the esophagus from the stomach in instances of glandular epithelial metaplasia. Ducts from these glands pierce the mucosa to drain into the esophageal lumen.

The muscularis propria is the muscular sleeve that provides the propulsive force necessary for swallowing. There are two layers of muscle: an inner circular layer and an outer longitudinal layer. The proximal 4% to 5% of the esophagus is composed completely of striated muscle and the distal 54% to 62% completely of smooth muscle.¹ Smooth muscle first appears in the anterior circular layer. The transition from striated to smooth muscle in the circular muscle layer is gradual, and the 50/50 point is approximately 5 cm from the cricopharyngeus muscle.

The cricopharyngeus (upper esophageal sphincter [UES]) is a continuous transverse band of muscle originating from the cricoid cartilage (Fig. 36-2). Superiorly, the muscle of the cricopharyngeus blends with the inferior pharyngeal constrictor muscle. A posterior defect, Killian triangle, is an inverted fan-shaped weakness in the inferior constrictor at the superior border of the cricopharyngeus. Inferiorly, the cricopharyngeus merges with the inner, circular layer of the muscularis propria. The longitudinal muscle layer of the muscularis propria originates from the lateral aspect of the cricoesophageal tendon. Posteriorly, these anterior and lateral components converge to meet at the midline. Thus, the proximal 1 to 2 cm of the posterior cervical esophagus is

FIGURE 36-2 ■ Esophageal musculature. EGJ, Esophagogastric junction.

composed only of inner circular muscle, creating a potential for a mirror-image triangular area of weakness called Laimer triangle.

Contraction of the longitudinal muscle fibers of the esophageal body produces esophageal shortening. The inner circular muscle is arranged in incomplete rings producing a helical pattern. Muscle layers are equal and uniform in thickness until the distal 3 to 4 cm of the esophagus. Here, the inner circular layer thickens and divides into incomplete horizontal muscular clasp on the lesser curve aspect of the distal esophagus and oblique sling fibers on the greater curve aspect. These become gastric sling fibers (see Fig. 36-2). Although no complete circular bands exist at the lower esophageal sphincter (LES), this area of rearranged circular fibers corresponds to the high-pressure zone of the LES.

The esophagus lies in a bed of fat, neurovascular, and connective tissue and elastic fibers termed the *adventitia*. This layer of loose connective tissue surrounding the esophagus contains lymphatics and regional lymph nodes, blood vessels, and nerves. Unlike the stomach, small bowel, and colon, it has no serosa, except in its short abdominal segment.

Lymphatics begin as blind endothelium-lined saccules in the lamina propria just below the epithelium and basement membrane. An immunohistochemical study of the esophageal wall using lymphatic endothelial marker D2-40 has provided insight into the lymphatic anatomy of the esophageal wall (see Fig. 36-1).² The lamina propria contains a dense longitudinal plexus of lymphatic vessels. Rare perforating lymphatics have been found

draining into a sparse circumferential lymphatic network in the outer margin of the submucosa. Perforating lymphatics from the submucosal plexus, usually running with an artery and vein, penetrate the inner circular layer of the muscularis propria. Here, they drain into a circumferential intramuscular plexus that accompanies the artery, vein, and nerves of this space. Afferent lymphatics, usually accompanied by an artery and vein, drain the intramuscular plexus into the lymphatic channels in the adventitia. No direct connection from the lamina propria network and the thoracic duct has been identified.² Existence of direct routes from mural lymphatics to the thoracic duct, without a relay through regional lymphatics and lymph nodes, has been documented by many authors; however, the exact patterns and occurrence of these pathways are highly variable.³⁻⁵

The arterial supply of the esophagus is parasitic. It is derived from blood vessels supplying other organs in the neck, chest, and abdomen. Generally, these vessels divide at a distance from the esophagus and send small segmental branches to that segment of the esophagus. Esophageal blood supply has three principal sources. The superior and inferior thyroid arteries supply the cervical esophagus. The proximal and middle thoracic esophagus receives blood from branches of the bronchial arteries. The only dedicated esophageal arteries are one or two branches that arise from the anterior aspect of the aorta below the tracheal carina. In one third of autopsy specimens, no esophageal artery could be identified.⁶ These esophageal arteries directly supply the lower thoracic esophagus. The lower thoracic esophagus and abdominal esophagus receive arterial branches from the left gastric and, occasionally, the splenic arteries. The combination of a segmented arterial supply derived from multiple sources and a rich intramural vascular plexus ensures an excellent esophageal blood flow and permits extensive esophageal mobilization without esophageal arterial insufficiency or ischemia. Because esophageal arteries branch from larger arteries some distance from the esophagus, stripping of the esophagus from its bed during transhiatal (blunt) esophagectomy is possible without direct ligation of the esophageal arterial supply. Arterial spasm provides adequate hemostasis; thus, significant bleeding does not complicate this procedure.

Subepithelial esophageal venules drain into a substantial submucosal venous plexus that extends the length of the esophagus.⁷ There are venous connections between the lower thoracic and abdominal esophagus and the portal venous system. Venules then pierce the muscularis propria to drain into veins on the surface of the esophagus. Regional drainage is directed to the inferior thyroid and brachiocephalic veins in the neck, the azygous and hemiazygous veins in the chest, and the left gastric and splenic veins in the abdomen.

Both parasympathetic and sympathetic nerves innervate the esophagus. Branches of the vagus nerve supply parasympathetic fibers that are motor to the muscle coat and secretomotor to the submucosal glands. The cervical and thoracic sympathetic chain and the celiac plexus provide sympathetic fibers that promote contraction of sphincters and relaxation of the esophageal body muscle, increase peristaltic and glandular activity, and cause

vasoconstriction. These fibers enter the esophageal wall with the blood supply and form fibers and ganglia within it. The myenteric (Auerbach) plexus is positioned between the longitudinal and circular layers of the muscularis propria and controls these muscles. The submucosal (Meissner) plexus controls the muscularis mucosa and submucosal glands.

Regional Anatomy

The esophagus spans the lower neck, thoracic cavity, and upper abdomen (Fig. 36-3). The anatomy of the esophagus is best divided into fifths: cervical, upper thoracic, middle thoracic, lower thoracic, and abdominal esophagus. The anterior wall of the cervical esophagus is in intimate contact with the posterior membranous trachea. The recurrent laryngeal nerves course anteriorly and laterally in the tracheoesophageal groove. The carotid sheaths bind the cervical esophagus laterally. The posterior wall of the cervical esophagus lies on the vertebral bodies.

The thoracic esophagus occupies the posterior mediastinum and passes anteriorly to the vertebral bodies. The upper thoracic esophagus lies posteriorly to the trachea and is bound laterally by the mediastinal pleura. In its lower left aspect, it is sandwiched between the azygous vein on the right and the aortic arch on the left. The middle thoracic esophagus lies behind the pulmonary hilum and between the azygous vein and descending aorta. The lower thoracic esophagus has the same lateral and posterior boundaries but lies behind the pericardium. The thoracic duct is situated between the azygous vein and descending thoracic aorta and posteriorly and to the right of the lower and midthoracic esophagus. At approximately the level of the fourth thoracic vertebra, it crosses the midline to become a left-sided structure.

The abdominal esophagus is cradled in the muscular esophageal hiatus. The inferior vena cava is on the right posterolateral aspect; the abdominal aorta is on the left posterolateral aspect. Superiorly, the left lateral segment of the liver overlies the esophagus and esophagogastric junction (EGJ).

ESOPHAGEAL FUNCTION

Swallowing has three phases: oral, pharyngeal, and esophageal. The action of swallowing is voluntarily initiated and is followed by a cascade of involuntary muscle activities that propels the swallowed bolus aborally. The esophageal phase of swallowing commences with the relaxation of the UES during the initiation of pharyngeal contraction. Food is pushed by pharyngeal contraction, and its transit is facilitated by negative intrathoracic pressure. Duration of UES relaxation is between 0.5 second and 1 second. After passage of the bolus, the UES contracts, reaching twice resting pressure.

A primary wave begins after a swallow stimulus and results first in immediate smooth muscle relaxation without increasing intraluminal pressure. Then, the contraction front begins and propagates antegrade at a speed

FIGURE 36-3 ■ Regional anatomy. **A**, Right mediastinal view. **B**, Left mediastinal view.

of 7 cm/sec in the proximal esophagus. However, the contraction front progressively slows to 2 cm/sec in the distal esophagus. This slowing is because latency until muscle contraction increases down the esophagus. The strength of the contraction increases with propagation along the esophagus. If impaction occurs, esophageal distention produces closure of the UES, and a secondary peristaltic wave begins at the site of obstruction and passes distally. Tertiary contractions are nonperistaltic contractions occurring spontaneously between swallows that are ineffective in antegrade bolus transit.

Resting pressure of the LES exceeds intragastric pressure and prevents reflux of gastric contents into the distal esophagus. Within 2 seconds of pharyngeal contraction, the LES relaxes to near intragastric pressure for 7 to 10 seconds. The LES then contracts to above resting pressure for 8 to 12 seconds before returning to resting pressure.

EVALUATION OF THE ESOPHAGUS

History and Physical Examination

The symptoms most commonly associated with esophageal diseases are heartburn, regurgitation, dysphagia, and odynophagia. Other symptoms that may be associated with esophageal disease are sore throat, hoarseness, cough, bad taste, globus, hiccup, aspiration, wheezing, chest pain, nausea, vomiting, choking, hematemesis, and melena. Symptom composition depends on the esophageal disorder and is discussed in various sections of this chapter. Physical examination of the esophagus is indirect

and focuses on head and neck, thoracic, and abdominal findings.

Box 36-1 lists systemic diseases with esophageal manifestations. Some are discussed later in this chapter. These potential underlying disorders should be considered during the history and physical examination.

Investigations

Patients with suspected esophageal disease will typically undergo barium esophagram and/or esophagoscopy as their initial diagnostic tests.

Barium Esophagram

A three-phase study assessing mucosa, contour, and function of the esophagus is optimal.⁸ In the double-contrast phase, conducted with the patient ingesting high-density barium and CO₂ tablets in the upright position, the mucosa is examined (**Fig. 36-4**). Next, esophageal function is assessed in the right anterior oblique (RAO) position with the ingestion of low-density barium in single swallows at 20- to 30-second intervals (**Fig. 36-5**). The examination is videotaped. The value of attempting to elicit reflux in this phase is questionable because 20% of normal individuals have radiologic reflux.⁹ Barium tablets or barium-coated marshmallows or solids may demonstrate abnormalities not visualized by liquid barium studies. The final phase, the full-column technique, is performed with the patient in a semiprone RAO position and low-density barium. Multiple quick swallows produce a column of barium that fully distends the esophagus. This optimizes imaging of the distal esophagus and can

FIGURE 36-4 ■ Barium esophagram: mucosa. Double-contrast phase of the barium esophagram provides mucosal definition. **A**, Patient with a hiatal hernia and peptic stricture; no significant ulceration is seen. **B**, Patient with a columnar-lined esophagus, distal peptic stricture, ulcers, and nodules.

Crohn disease

demonstrate small hiatal hernias, subtle strictures, or distal rings (Fig. 36-6). The esophagus is allowed to empty, and the remaining barium coating the esophageal wall provides a mucosal relief study, now rarely performed.

The timed barium esophagogram is a simple test of esophageal emptying (Fig. 36-7). After the patient ingests

a premeasured amount of barium, usually 250 mL, spot films are taken at 1-, 2- and 5-minute intervals and, if necessary, at 10 minutes and 20 minutes after barium ingestion. This allows simple quantification of esophageal emptying and is useful for evaluations of both motility disorders and the results of therapy.^{10,11}

FIGURE 36-5 ■ Barium esophagram: function. Single swallows every 20 to 30 seconds in the right anterior oblique semiprone position assesses esophageal function. **A**, Patient with diffuse esophageal spasm (corkscrew esophagus). **B**, Patient with abnormal motility and a midthoracic diverticulum.

FIGURE 36-6 ■ Barium esophagram: contour. The full column phase of the barium esophagram fills and fully distends the esophagus, providing an examination of esophageal contour. **A**, Patient with an obstructed esophagus caused by a peptic stricture and associated nonreducible hiatal hernia. **B**, Patient with a Schatzki ring. **C**, Patient with achalasia.

FIGURE 36-7 ■ Timed-barium esophagram. **A**, Before Heller myotomy, patient was able to ingest only 70 mL of the requested 250 mL barium. Height (barium-coated saliva not included) and width of the column are measured at 1, 2, and 5 minutes after ingestion. Note markedly delayed esophageal emptying and incomplete emptying at 5 minutes. **B**, After Heller myotomy, ingestion of 70 mL of barium resulted in trace barium in the esophagus at 1 and 2 minutes and clearance by 5 minutes.

Esophagoscopy

Esophagoscopy is used to visually assess mucosal and structural esophageal abnormalities. Biopsies of epithelial abnormalities such as esophagitis, mucosal nodules, columnar cell-lined segments, and strictures are an integral part of flexible fiberoptic esophagoscopy. However, the biopsies are limited to the mucosa. Indirect evidence of deeper mural abnormalities or extraesophageal lesions may be appreciated by extrinsic compression or displacement of the overlying epithelium. Endoscopic resection, either mucosal resection (EMR) or submucosal dissection (ESD), is an endoscopic alternative to surgical resection in the diagnosis and management of some esophageal lesions. In benign esophageal diseases, endoscopic resection is used most commonly in evaluating lesions in patients with Barrett esophagus.¹²

Esophageal Manometry

Esophageal manometry is indicated (1) to establish the diagnosis of dysphagia when obstruction and eosinophilic esophagitis have been excluded, (2) for placement of intraluminal devices such as a pH probe, and (3) before antireflux surgery. It is possibly indicated for dysphagia after antireflux surgery or therapy for achalasia.¹³ High-resolution manometry (HRM) is a major advance over traditional low-resolution manometry in that it has increased the number of pressure sensors from 5 to 36, has decreased the distance between sensors from 5 to 1 cm, and includes sensors in the pharynx and proximal stomach (Fig. 36-8). Sophisticated computer algorithms extrapolate between these sensors, permitting a continuous, seamless assessment of intraluminal esophageal pressure from pharynx to stomach. The display of intraluminal pressure as a color spectrum on a plot of esophageal

FIGURE 36-8 ■ Manometry catheter types. **A**, The traditional low-resolution manometry catheter has five pressure sites located in the lower esophageal sphincter (LES) and 5, 10, 15, and 20 cm above the LES. **B**, Impedance manometry has impedance pairs at the four esophageal pressure sites of the low-resolution manometry catheter. **C**, The high-resolution manometry catheter has 36 pressure sites 1 cm apart that extend from pharynx to stomach.

position (y axis) against time (x axis) produces a pressure topography of swallowing (Fig. 36-9). Catheter placement is easier, and study duration is markedly shorter by eliminating the LES pull-through. As a result of these features, this technology has had widespread adoption into clinical practice.

HRM accurately measures LES relaxation by compensating for LES movement with swallows. HRM also determines latency until esophageal contraction after a swallow stimulus to assess for premature contractions, as well as multiple smooth muscle contraction parameters

FIGURE 36-9 ■ High-resolution manometry topograph derived from 36 pressure sites 1 cm apart. The left side of the figure shows several topographic metrics. Distal latency (white arrow) is the duration from swallow onset (vertical white line) to where peristalsis decelerates (5 sec; normal, >4.5 sec). Contractile vigor (DCI [distal contractile integral] box) is average pressure (mm Hg) × duration (sec) × height (cm) (2650; normal, 450-5000 mm Hg/sec/cm). Isobaric contour at 20 mm Hg (black curved line) shows no large (>5 cm) or small (2-5 cm) waveform defects. The right side of the figure divides the tracing into anatomic segments from pharynx to stomach. The pharynx is from 16 to 18 cm, and pharyngeal contraction (black arrow) occurs as the upper esophageal sphincter (UES) (18-20 cm) relaxes after a 5-mL swallow, and the UES pressure falls from 50 to 0 mm Hg. The striated muscle contraction wave begins as the UES recovers, and advances from 21 to 24 cm, where a transition zone (24-26 cm) of lower pressure occurs. The smooth muscle peristaltic contraction wave extends from 26 to 44 cm, is antegrade (3 cm/sec; normal, <9), and normal in amplitude (50-75 mm Hg; normal, <180), duration, and intrabolus pressure. The lower esophageal sphincter (LES) extends from 44 to 47 cm, relaxes just after a swallow occurs from 15 mm Hg to near 0, and then overshoots to 30 mm Hg.

(antegrade peristalsis, amplitude, intrabolus pressure). These and other topographic metrics are shown in Figure 36-9. Table 36-1 lists the Chicago Classification Criteria of Esophageal Motility Disorders based on these topographic metrics and agreed on by an international panel of experts.¹⁴ More extensive discussion of HRM (e.g., detailed assessment of EG junction morphology allowing separation of LES and diaphragm [for detecting hiatal hernia, etc.]), other metrics, and use in lap band surgery is available elsewhere.¹⁴⁻¹⁶ Continued experience with HRM and especially outcome data should allow refinements in the classification scheme in the future.

Impedance Manometry

The traditional impedance manometry catheter adds an impedance pair at each of the four esophageal pressure sites of the low-resolution manometry catheter (see Fig. 36-8). This catheter allows bolus transit to be compared with simultaneous esophageal peristalsis and contraction amplitude and is termed the *esophageal function test* (Fig. 36-10).¹⁷ In 350 patients studied at a single

center, all with achalasia and scleroderma had abnormal bolus transit and more than 95% of those with normal manometry, nutcracker esophagus, and LES dysfunction (high or low) had normal bolus transit.¹⁸ Recently, a catheter with both high-resolution manometry (36 sites, 1 cm apart) and high-resolution impedance (18 impedance pairs) capability was developed to improve on the low resolution of the esophageal function test catheter. A classification of weak peristalsis has been proposed based on this newly developed catheter's ability to correlate abnormalities in peristaltic integrity with failed bolus clearing.¹⁹

Ambulatory Conventional and Wireless pH Monitoring

Ambulatory pH monitoring detects and quantifies acid gastroesophageal reflux. Because this test is typically performed without acid suppression medication, proton pump inhibitors (PPIs) should be discontinued for 1 week, H₂ blockers for 24 hours and antacids for 8 hours. Conventional transnasal monitoring is done for 24 hours

with the thin pH catheter placed 5 cm above the LES, located by manometry. Patients are instructed to have a “typical day” regarding activity and eating. Because symptom correlation is an important component of this test, the patient presses a symptom button when symptoms occur.

TABLE 36-1 Chicago Classification Criteria of Esophageal Motility Disorders

Diagnosis Criteria

Achalasia

- Type I achalasia—Mean IRP > 15 mm Hg, 100% failed peristalsis
- Type II achalasia—Mean IRP $\geq$ 15 mm Hg, aperistalsis, panesophageal pressurization $\geq$ 20%
- Type III achalasia—Mean IRP $\geq$ 15 mm Hg, aperistalsis, spastic contractions $\geq$ 20% swallows
- EGJ outflow obstruction—Mean IRP $\geq$ 15 mm Hg, some normal or weak peristalsis

Motility Disorders (Defined as Pattern not Seen in Normal Individuals)

- Distal esophageal spasm—Normal mean IRP, $\geq$ 20% premature contractions (DL < 4.5 sec)
- Jackhammer esophagus—At least one swallow DCI > 8000 with single or multi-peaked contraction
- Absent peristalsis—Normal mean IRP, 100% swallows with failed peristalsis

Peristaltic Abnormalities (Defined by Exceeding Statistical Limits of Normal)

- Weak peristalsis:
 - Large peristaltic defects—Mean IRP < 15 mm Hg and >20% swallows with >5-cm breaks in 20-mm isobar
 - Small peristaltic defects—Mean IRP < 15 mm Hg and >30% swallows with 2- to 5-cm breaks in 20-mm isobar
- Frequent failed peristalsis—>30%, but <100% of swallows with failed peristalsis
- Rapid contractions with normal latency—Rapid contractions > 20% swallows, DL > 4.5 sec
- Hypertensive peristalsis—Mean DCI > 5000, but lacks hypercontractile (jackhammer) criteria (also termed *nutcracker*)

Normal (Not Achieving any of the above Diagnostic Criteria)

DCI, Distal contractile integral; DL, distal latency; EGJ, esophagogastric junction; IRP, integrated relaxation pressure; LES, lower esophageal sphincter.

IRP: Lowest average pressure of 4 seconds within the LES window. Modified from Bredenoord A, Fox M, et al: *Chicago classification criteria of esophageal motility disorders defined in HRM esophageal pressure topography*. *Neurogastroenterol Motil* 24(Suppl 1):57–65, 2012.

A pH less than 4 has arbitrarily been chosen to define an acid reflux episode. The normal parameters for 24-hour pH monitoring have been defined (Table 36-2). Total acid exposure time, expressed as a percentage of study time, is the best discriminator between normal and abnormal values.²⁰ Composite scores, such as the DeMeester score and frequency-duration index, are no better than simple measured parameters in identifying abnormal reflux. The symptom index relates symptoms to reflux events and is calculated by dividing symptom episodes with reflux by the total number of symptom episodes multiplied by 100%; 50% is the optimum threshold.²¹

Wireless pH monitoring is a recent technological advance. The Bravo delivery system “pins” a capsule measuring $6 \times 5.5 \times 25$ mm to the esophagus 6 cm above the squamocolumnar junction, identified by endoscopy. Manometry is not required. Improved patient tolerance allows increased activities and improved food intake; moreover, monitoring is traditionally extended to 48 hours (Fig. 36-11).²² Wireless pH monitoring has an increased diagnostic yield compared with transnasal monitoring because of higher sensitivity for both abnormal acid exposure and positive symptom-reflux association.²³ Drawbacks are cost, occasional premature detachment, and severe pain requiring endoscopic removal in less than 2% of cases. Similar to nasal pH monitoring, wireless pH monitoring is unable to detect nonacid reflux.

Impedance-pH Monitoring

When an ionic fluid bolus traverses an electrode pair, impedance to current flow decreases. Impedance pairs placed on a pH catheter at multiple sites can detect retrograde fluid flow throughout the esophagus as acid reflux if the pH is less than 4 or as nonacid reflux if pH is greater than 4.²⁴ An expert panel concluded that impedance-pH monitoring off PPI therapy is the best test to detect all reflux episodes in a patient,²⁵ and thus is the best test for symptom association in patients with gastroesophageal reflux disease (GERD). The test has limitations, such as the necessity of a nasal catheter, and low baselines in esophagitis or Barrett esophagus make interpretation difficult. Moreover, currently available software for automated detection of reflux episodes is sensitive but not very specific, and manual editing is recommended at this time.²⁶

TABLE 36-2 Normal Distal Values for 24-hour pH Monitoring

Parameter	Johnson ³¹³ 95th Percentile	Richter ³¹⁴ 95th Percentile	Jamieson ³¹⁵	
			Mean	Percentile
Total time (%)	4.45	5.78	4.5	95
Upright time (%)	8.42	8.15	7.1	93
Supine time (%)	3.45	3.45	1.5	86
No. of episodes	47	46	56	98
No. >5 min	3	4	3	94
Longest episode (min)	19.8	18.5	12	84
Composite score	14.7	—	16.7	96

FIGURE 36-10 ■ Simultaneous impedance and manometry showing normal bolus transit after each of three 5-mL saline swallows. Bolus entry occurs at each of four impedance sites as impedance decreases (see first vertical line in second swallow). Antegrade decrease in impedance in the four sites shows normal bolus advance through the esophagus. After bolus persistence with a low impedance value, a rise in impedance toward baseline occurs at each site from bolus clearing (see second vertical line in second swallow) as a result of simultaneous esophageal contraction at the same level. Antegrade increase in the four impedance sites shows normal bolus clearing from the esophagus. Normal lower esophageal sphincter (LES) relaxation and overshoot is seen.

Impedance-pH monitoring on PPI therapy has been used when suspected esophageal and/or extraesophageal reflux symptoms persist despite PPIs (Fig. 36-12). Small case series in patients with a positive symptom index have shown good results after fundoplication.²⁷ However, we believe long-term controlled studies first performed in centers with experience in impedance-pH monitoring are needed to identify the role of such monitoring when only symptom association and nonacid reflux are found.

Endoscopic Esophageal Ultrasound

Endoscopic esophageal ultrasound (EUS) provides definition of the esophageal wall and periesophageal tissue not possible to obtain with routine fiberoptic esophagoscopy. It is indispensable in evaluating abnormalities of the esophageal wall and diagnosing nonmucosal esophageal tumors. Ultrasound endoscopes scan the wall with ultrasound waves of 5 to 12 MHz. Probes, which can be passed through the biopsy channel of flexible endoscopes, can evaluate esophageal strictures that prevent passage of standard ultrasound equipment. The esophagus and periesophageal tissues are viewed as five alternating layers of different echogenicity (Fig. 36-13). This examination also provides images of periesophageal structures, includ-

ing regional lymph nodes. Both the layer of origin and ultrasound characteristics of a mass are critical in diagnosing benign esophageal tumors. Periesophageal masses and regional lymph nodes can also be studied. EUS-directed fine-needle aspiration (FNA) provides cytologic and pathologic assessment of esophageal tumors, periesophageal masses, and regional lymph nodes.

BENIGN ESOPHAGEAL DISEASES AND THEIR TREATMENT

Hiatal Hernia

Herniation of abdominal contents through the esophageal hiatus is a common occurrence. With provocative maneuvers that increase intra-abdominal pressure, 55% of patients undergoing barium esophagram were found to have herniation of the stomach into the chest.²⁸ Symptoms are secondary to reflux, incarceration or strangulation of herniated organs, or compression of thoracic structures. There are four types of hiatal hernia, each with its own symptom presentation. Type I, or sliding hiatal hernia, is the most common (see Figs. 36-6A and

FIGURE 36-11 ■ Example of 48-hour Bravo pH monitoring in a symptomatic patient with suspected GERD. Severe (day 1) and moderate (day 2) bipositional acid exposure is present, as well as positive symptom index (>50%) for heartburn and regurgitation.

FIGURE 36-12 ■ Simultaneous impedance and pH monitoring shows two nonacid liquid reflux episodes in patient receiving acid suppression. The first shows retrograde liquid reflux to 9 cm above the lower esophageal sphincter (LES) (down arrows), and subsequent clearance after 2 minutes at all sites (up arrows). The second shows retrograde liquid reflux to the most proximal site, and cough occurs 40 seconds later.

FIGURE 36-13 ■ Esophageal wall is visualized as five alternating layers of differing echogenicity by esophageal ultrasound. The first (inner) layer is hyperechoic (*white*) and represents the superficial mucosa (epithelium and lamina propria). The second layer is hypoechoic (*black*) and represents the deep mucosa (muscularis mucosae). The third layer is hyperechoic and represents the submucosa. The fourth layer is hypoechoic and represents the muscularis propria. The fifth layer is hyperechoic and represents the paraesophageal tissue. The thickness of ultrasound layers does not equal the actual thickness of the anatomic layers.

36-14). Herniation of the EGJ into the posterior mediastinum occurs because of thinning and elongation of the phrenoesophageal ligament. There is no potential for incarceration. Most patients with type I hiatal hernias are asymptomatic. If symptoms occur, they are GERD related. Type II, or rolling, hiatal hernias are uncommon (Fig. 36-15). They result from a defect in or isolated weakness of the phrenoesophageal ligament, allowing a portion of the stomach to herniate through the hiatus while the EGJ remains anchored in the abdomen. Symptoms of gastric obstruction, strangulation, anemia, and, less commonly, shortness of breath and arrhythmia result from gastric herniation through the hiatus and presence of the stomach in the chest. Type III, or mixed, hiatal hernias are the second most common type (Fig. 36-16). Patients may present with reflux, symptoms of type II hernias, or both. As type III hernias increase in size, there may be organoaxial volvulus with the potential for strangulation. In many patients, these hernias may be a progression of type I hernias.²⁹ Type IV hiatal hernias contain the stomach and other abdominal contents such as colon, spleen, small bowel, and pancreas (Fig. 36-17). The term *paraesophageal hernia* is sometimes used to describe any type II, III, or IV hiatal hernia.

Symptomatic hiatal hernias should be repaired. Repair of asymptomatic types II and III hernias is controversial. The potential for strangulation and gastric necrosis has been advocated as the primary reason to repair paraesophageal hernias in all patients, particularly because a 50% mortality rate was initially reported when this complication occurred.³⁰ However, strangulation is an uncommon occurrence without antecedent symptoms; therefore, this is an overestimate, and careful follow-up of asymptomatic patients is a viable alternative to repair in all patients.

Repair follows the principles of surgical treatment of GERD. Addition of a fundoplication is controversial but is definitely indicated if symptomatic GERD is present. Laparoscopic repairs have been reported to have an earlier and increased rate of failure.³¹ A meta-analysis showed this to be 25% at variable follow-up.³² This high incidence of recurrence has prompted the use of various types of mesh reinforcement of laparoscopic hiatal reconstruction. Although mesh has been reported to decrease recurrence at 6 months but not at 5 years,^{33,34} the clinical significance of these early findings³⁵ and long-term durability^{36,37} are in question. In most patients, addition of a gastrostomy or gastropexy is not required. Compared

FIGURE 36-14 ■ Type I hiatal hernia. **A**, Pictorial presentation. **B**, Retroflexed view from the intra-abdominal stomach at esophagoscopy. Diaphragmatic impression and intrathoracic stomach can be seen.

FIGURE 36-15 ■ Type II hiatal hernia.

with GERD patients, patients with type III hiatal hernias are older and have more comorbidities. Adjusting for these factors demonstrates that patients with type III hernias are more likely to have pulmonary, thromboembolic, and bleeding complications in their postoperative course than those with type I hiatal hernias.³⁸

Gastroesophageal Reflux Disease

GERD was defined at the Montreal consensus conference as “a condition which develops when the reflux of stomach contents causes troublesome symptoms and/or complications.”³⁹ The diagnosis is made through some combination of symptom presentation, objective testing

with endoscopy, ambulatory reflux monitoring, and response to antireflux therapy.

Typical symptoms of GERD are heartburn, regurgitation, and dysphagia. Patients with noncardiac chest pain suspected to be caused by GERD should have a cardiac cause excluded before starting a gastrointestinal evaluation. Extraesophageal symptoms/disorders of which GERD is a potential co-factor are asthma, chronic cough, and laryngitis, although a diagnosis of reflux laryngitis should not be made solely based on laryngoscopic findings.⁴⁰ Other atypical symptoms/disorders (pulmonary fibrosis, pharyngitis, otitis media, and sinusitis) are often linked to reflux and are proposed associations, but data are insufficient to establish causation.³⁹ It is important that abdominal pain, gas, and bloating not be misinterpreted as GERD symptoms.

Complicated GERD includes reflux esophagitis, esophageal stricture, and Barrett esophagus. The mucosal response to acid may produce intestinal metaplasia (Barrett esophagus), and damage to the submucosa and muscularis propria can result in a short esophagus (see Fig. 36-4 and 36-6A). Peptic stricture and high-grade dysplasia or intramucosal carcinoma developing in Barrett epithelium are the most feared complications of GERD.

The LES and diaphragmatic hiatal mechanism are the major components of the reflux barrier.^{41,42} A hiatal hernia is seen in 50% to 90% of patients with GERD.⁴³⁻⁴⁶ However, reflux events are most commonly the result of transient LES relaxations, although reflux over a low basal LES is also important.⁴⁷ Poor acid clearance from peristaltic dysfunction and delayed gastric emptying contribute to prolonged acid exposure in some patients.

The mainstay of therapy for GERD is medical management. Randomized studies do not demonstrate a superiority of surgery over medical therapy.⁴⁸⁻⁵⁰ Weight

FIGURE 36-16 ■ Type III hiatal hernia. A barium esophagram demonstrates a type III hiatal hernia with organoaxial rotation. **A**, Posteroanterior view. **B**, Lateral view.

loss for those who are overweight, head of bed elevation for recumbent symptoms, and other lifestyle modifications tailored to the individual are suggested.⁵¹ An 8-week course of PPIs is the therapy of choice for symptom relief and healing of erosive esophagitis. PPIs can heal esophagitis in more than 90% of patients. Maintenance PPI therapy is appropriate for GERD patients with continued symptoms after PPI is stopped and in patients with complications such as Barrett esophagus and erosive esophagitis,⁴² because most with Los Angeles (LA) grade B-C esophagitis will relapse by 6 months.⁵² There is insufficient evidence to recommend for or against endoluminal antireflux procedures⁵¹ or transoral incisionless fundoplication as an alternative to medical or traditional surgical therapy.⁴⁰ However, sphincter augmentation with the LINX management system for selected patients is promising and more data are eagerly awaited.^{53,54}

Atypical symptoms/disorders respond less predictably to PPIs, especially in the absence of typical symptoms. Patients with extraesophageal symptoms who have concomitant typical symptoms, moderate-sized hiatal hernias, and moderate reflux on pH testing may respond better to acid suppression. PPI failures usually have causes other than GERD.⁵⁵ The increased incrimination of GERD as a causative factor for extraesophageal syndromes along with the lack of accurate confirmatory diagnostic tests has resulted in widespread overdiagnosis and overtreatment of these conditions.⁵¹

Surgical management of GERD is a treatment option for long-term therapy in GERD patients. It should be considered in patients who are noncompliant, experience side effects from medical therapy, or have esophagitis refractory to medical therapy.⁴⁰ Surgical therapy is generally not recommended in patients who do not respond to PPI therapy⁴⁰ except for highly selected patients,

especially those with persistent and severe “volume regurgitation.”⁵¹

The following preoperative GERD evaluation is suggested. First, endoscopy should be performed to assess for presence of esophagitis, Barrett mucosa, stricture, hiatal hernia, and alternative upper GI diagnoses such as ulcer disease. Second, manometry should be performed to locate and measure LES, exclude another diagnosis such as esophageal spasm, and assess peristalsis. Third, ambulatory pH monitoring off therapy should be performed to confirm excessive acid exposure in those patients without LA class C-D erosive esophagitis or Barrett esophagus. Typical symptoms that respond to PPI therapy and abnormal acid exposure as determined by pH monitoring are reliable predictors of successful surgical treatment of GERD.^{56,57} We typically also do barium esophagram to assess anatomy of the esophagus and EGJ, mucosal changes, and esophageal function. In patients with suspected gastric drainage abnormalities, a nuclear medicine gastric emptying study is required.

Surgical management is less likely to be effective in patients with persistent atypical symptoms/disorders. Recent guidelines suggest surgery should generally not be performed to treat extraesophageal symptoms of GERD in patients who do not respond to acid suppression with optimal use of PPIs.⁴⁰ Instead, non-GERD causes should be pursued. Although small case series have shown good results for antireflux surgery in patients with persistent cough on PPIs and a positive symptom index for cough and nonacid reflux by impedance-pH monitoring,⁵⁸ long-term controlled studies are needed to validate this approach.⁵⁹

Complicated GERD is first managed with aggressive medical therapy; however, peptic esophageal stricture and chronic Barrett ulcer may require surgery. The

FIGURE 36-17 ■ Type IV hiatal hernia. **A**, Barium esophagram demonstrates a type III hiatal hernia with organoaxial rotation. Three days later, barium is seen in colonic diverticulum on preoperative chest radiograph. **B**, Posteroanterior view. **C**, Lateral view. Therefore, this is a type IV hiatal hernia.

columnar cell-lined esophagus is not in itself an indication for surgery. However, patients with Barrett esophagus should have endoscopic surveillance for detection of dysplasia.⁶⁰ It is debatable that surgery can reverse the changes of columnar lining. Partial reversal, although interesting, is not a compelling argument for surgical correction of GERD.⁶¹ Therefore, either prevention of or halting malignant degeneration in a columnar cell-lined esophagus is not an indication for surgery. If a patient with a columnar cell-lined esophagus has antireflux surgery, the need for endoscopic surveillance is not eliminated. Therefore, the patient with a columnar cell-lined esophagus has the same indications for surgery as

the patient with a squamous-lined esophagus, although they often have the most disordered physiology, largest hernias, and most disrupted hiatal mechanisms.⁶²

The principles of antireflux surgery are restoration of the intra-abdominal length of esophagus, reconstruction of the esophageal hiatus, and reinforcement of the LES.⁶³ These can be accomplished by a number of approaches and techniques. Possible approaches, in descending order of morbidity, are thoracoabdominal, thoracotomy, laparotomy, and laparoscopy. Facility with all of these approaches is necessary.

Restoration of the intra-abdominal esophagus requires reducing the hiatal hernia and mobilizing the esophagus.

This portion of the operation necessitates recognition of the short esophagus.⁶⁴ Failure to lengthen the short esophagus by extensive esophageal mobilization to the aortic arch or by addition of a Collis gastropasty will result in a repair under tension and early failure. The short esophagus should be suspected by history of a stricture or previous dilation or findings of a long segment columnar cell-lined esophagus, a large type I hiatal hernia (>4 cm), a type III hiatal hernia, or failure of the hernia to reduce below the diaphragm on upright barium esophagram.

The importance of reconstruction of the hiatus cannot be underestimated. It plays a role in reflux prevention equal to that of the LES.⁶⁵ The recent addition of mesh reinforcement of the hiatal closure ignores the past history of antireflux surgery and the dynamic nature of this structure. Complete mobilization of the hiatal crura and careful removal of the hernia sac will allow primary suture reconstruction of the hiatus. Failure to reconstruct the hiatus is a common cause of failure of laparoscopic antireflux surgery.⁶⁶ The principal reason for reherniation after an otherwise adequate repair is usually tension on the repair (because the short esophagus was either ignored or not recognized) and not an unbuttressed reconstruction of the hiatus.

The final step in the surgical correction of GERD is reinforcing the LES by constructing a fundoplication, which may be either total or partial. The Nissen fundoplication, which is a 360-degree total fundoplication, completely encircles the esophagus. Partial fundoplication is typically 270 degrees and is either anteriorly placed (Belsey Mark IV repair) or posteriorly placed (Toupet repair). Theoretically, the trade-off is between better reflux control with a total fundoplication or less dysphagia with a partial fundoplication. Some surgeons tailor the fundoplication to suit the peristaltic activity of the esophageal body.⁶⁷ HRM and concomitant high-resolution impedance to assess bolus transport should allow a more precise cutoff at which the severity of peristaltic dysfunction requires partial fundoplication.¹⁹ Until this can be accomplished, we consider total fundoplication to be appropriate for all except the patient with an aperistaltic esophagus.⁶⁸⁻⁷² Use of a partial fundoplication in the presence of complicated GERD is associated with increased incidence of failed repairs.⁷³ Dysphagia following surgery for GERD is usually transient with a properly constructed fundoplication. Prolonged dysphagia is indicative of a malformed fundoplication—long, tight, or twisted. Return of normal esophageal motility with resolution of GERD following fundoplication is hypothetically possible. It is more likely that the amplitude of the peristaltic wave will increase than failure of propagation will be corrected. Therefore, any fundoplication should be constructed assuming the peristaltic abnormalities will not improve. Finally, the potential for postprandial symptoms of gas bloat and early satiety must be mentioned to any patient being considered for fundoplication.

An ignored but essential part of physical examination is measuring and recording weight and height and calculating body mass index (BMI). Overweight (BMI, 25 to 29) and obese (BMI, 30 to 34) patients with GERD should be counseled on weight loss and encouraged to

reach their ideal weight before elective surgery. Because obesity and GERD are interrelated,^{74,75} successful and sustained weight loss may eliminate the need for surgery. Although there is disagreement concerning the impact of obesity on the outcome of antireflux surgery,⁷⁶⁻⁸¹ health benefits of weight loss in severely (BMI, 35 to 39) and morbidly (BMI, ≥40) obese GERD patients should make weight loss surgery the operation of choice in these patients.

Antireflux operations are not infinitely durable. It is important that all patients be instructed to avoid activities that excessively increase intra-abdominal pressure and to maintain their ideal weight.⁸² Unrealistic patient expectations and widespread application of laparoscopic fundoplication without careful patient selection in low-volume centers by inexperienced surgical teams have produced poor results and have had a negative impact on this operative approach.⁸³⁻⁸⁵

Motility Disorders

Achalasia

Achalasia is an uncommon and incurable neurodegenerative esophageal motility disorder of unknown cause, which affects both sexes and all races equally.^{86,87} Achalasia results from damage to the myenteric plexus with selective destruction of inhibitory neurons in the myenteric plexus by cytotoxic T lymphocytes.⁸⁸⁻⁹² The inflammatory neurodegenerative insult causes an imbalance between excitatory and inhibitory neurons, cumulating in aperistalsis of the esophageal body and failure of LES relaxation.⁹³ Most patients complain of progressive dysphagia to solids and liquids and regurgitation. Weight loss is a common sequel, depending on the disease duration.⁹⁴ Retrosternal discomfort is common; significant chest pain affects some patients and may persist although other symptoms improve after successful therapy. Recurrent respiratory infection, aspiration pneumonia, and lung abscess may be initial presentations and often herald advanced disease. Most patients seek medical attention only after significant and irreversible damage to the esophageal myenteric neural plexus has occurred.

Barium esophagram and esophagoscopy are usually the first diagnostic tests performed because the usual symptoms are dysphagia and regurgitation. Classic findings on esophagram are esophageal dilation, aperistalsis, impaired esophageal emptying, and symmetrical tapering at the EGJ (bird's beak or ace of spades appearance) (see Fig. 36-6C). Timed barium esophagram allows quantification of esophageal obstruction and emptying (see Fig. 36-7). Esophagoscopy usually shows some degree of food or fluid retention (occasionally only saliva), chronic stasis changes, and a tight, spastic or puckered EGJ, not restricting endoscope passage. When achalasia is suspected, endoscopy is essential to exclude benign or malignant strictures, particularly pseudoachalasia (esophageal obstruction secondary to malignancy), which may be clinically and manometrically indistinguishable from primary achalasia.⁹⁵

Esophageal manometry confirms achalasia when suggested by symptoms and other studies mentioned earlier.

Manometrically, achalasia is defined by incomplete or failed relaxation of the LES and aperistalsis of the esophageal body.^{14,96} Resting LES pressure can be normal in up to 50% of patients; therefore, elevated LES pressure is not required for diagnosis.^{14,97,98} HRM has recently identified three subtypes of achalasia based on different biomechanics and treatment responses (Fig. 36-18). Type I (classic) has minimal or no esophageal pressurization or peristaltic activity; type II demonstrates panesophageal pressurization, greater than 30 mm Hg, throughout the entire esophagus in at least 20% of sequences; and type III (spastic, vigorous) is associated with 20% or more swallows associated with premature contractions.^{14,99,100} Type II achalasia has been reported to be a predictor of an excellent outcome after all available treatment modalities. Type I patients do significantly better with Heller myotomy than with pneumatic dilation. Type III and pretreatment esophageal dilation were predictive of poorer outcomes.¹⁰¹⁻¹⁰⁴ Although retrospective studies show that these subtypes can predict clinical outcome, it is unclear if the subtyping has clinical impact such as for clinical decision making.^{99,105}

Treatment of achalasia is palliative, aimed at reducing the esophageal outflow obstruction caused by the nonrelaxing LES to improve esophageal emptying. Goals of therapy are symptom relief, improving esophageal emptying by barium radiographs,¹⁰⁶ and preventing progression to megaesophagus. To accomplish this, achalasia patients require follow-up by their gastroenterologist or surgeon every 1 to 2 years for subjective and objective evaluation. Variable emptying in patients with achalasia is possible,¹⁰⁷ but repeated studies in the long-term follow-up are valuable.

Available treatment options include pharmacologic, endoscopic, and surgical means tailored to each patient.

Oral pharmacologic options are the least effective. Calcium channel blockers, long-acting nitrates, and phosphodiesterase-5-inhibitors transiently relax the LES pressures and may provide short-acting but incomplete relief of symptoms. Frequent and unpleasant side effects along with development of tolerance are the major limiting factors for their use.¹⁰⁸⁻¹¹⁰

Endoscopic injection of botulinum toxin (a potent inhibitor of acetylcholine release from nerve endings) has been used to treat achalasia with approximately 50% reduction in LES pressure.^{108,111} Palliation is temporary, lasting a mean of 6 months, with recurrent symptoms in more than 50% of patients.^{112,113} Resistance to repeat injections is thought to result from antibody production against botulinum toxin. Use of botulinum toxin may complicate future surgery because it causes inflammation and fibrosis in the plane between the submucosa and the muscularis propria, resulting in difficulty in the dissection of the submucosal plane.¹¹⁴⁻¹¹⁶ Although this may result in increased intraoperative mucosal perforation rate, there does not seem to be an increase in length of hospital stay or postoperative symptoms. This therapy is reserved for patients who cannot tolerate more aggressive forms of treatment, as a bridge to more definitive treatment or for intractable achalasia-associated chest pain.

Pneumatic dilation and surgical myotomy are the two most effective treatment modalities for achalasia. Pneumatic dilation with the modern Rigidflex balloon dilator (balloon diameters of 3.0, 3.5, and 4.0 cm) is successful in controlling symptoms in 50% to 93% of patients.¹¹⁵ A graded dilator approach with 3.0 cm, 3.5 cm, and 4.0 cm results in good-to-excellent response rates of 74%, 86%, and 90%, respectively, with an average follow-up of 1.6 years (range, 0.1 to 6 years).¹¹⁰ A recent summary of 22 studies with 1212 patients treated with

FIGURE 36-18 ■ Three achalasia subtypes. *Type I* has no contraction identified in the smooth muscle portion of the esophagus. Lower esophageal sphincter pressure (LESp) is greater than 30 mm Hg, and LES relaxation is never less than 20 mm Hg (normal, <15). *Type II* has esophageal pressurization greater than 40 mm Hg extending from upper esophageal sphincter (UES) to the LES that is simultaneous and repetitive. *Type III* has a prolonged, simultaneous, high-amplitude contraction characteristic of “vigorous achalasia.” The contraction does not extend from UES to LES as in type II.

Rigiflex balloon dilation reported a 2.0% perforation rate and 78% good or excellent results at 3-year follow-up. More than a third of patients will have symptom recurrence during a 4-year period, but they may respond to repeat dilation.¹¹⁷

Open modified Heller myotomy performed transabdominally or transthoracically has been successful in treating achalasia. Two prospective studies have been reported comparing pneumatic dilation to myotomy.^{118,119} After 4.8 years of follow-up, laparotomy and myotomy provided symptom control in 95% of patients, whereas pneumatic dilation with the Mosher system provided symptom control in 65%.¹¹⁸ In a small randomized study of 40 patients, no difference was observed between modalities, except that myotomy was associated with a lower LES pressure and less reflux.¹¹⁹

Development of laparoscopic Heller myotomy has resulted in more patients being referred for surgery and fewer for pneumatic dilation.¹²⁰ Laparoscopic Heller myotomy results in a shorter hospital stay.¹²¹ Improved outcome is associated with increased surgical volume. With short follow-up (mean, 1 year), good to excellent symptom control is seen in 94% of patients, but 11% report reflux.¹¹⁶ A recent review of 33 published studies of laparoscopic Heller myotomy reported that 85% of 1812 patients had a good to excellent response at a mean follow-up of 32 months, and 17% reported GERD as a postoperative complication.¹¹⁷ Preoperative pneumatic dilation has been reported to increase the risk of intraoperative esophageal perforation during laparoscopic Heller myotomy.¹²²

Regardless of surgical approach, the extent of myotomy is critical to good long-term outcome. A 3-cm extension of the myotomy onto the stomach is superior to a lesser myotomy for symptomatic and physiologic effects.¹²³ Controversy continues regarding the need for fundoplication added to myotomy. A fundoplication has been reported to be less essential when a thoracotomy is used. This finding most likely reflects a lesser myotomy. However, with the adoption of longer extensions of the myotomy onto the stomach, it is prudent to add a partial fundoplication to reduce reflux. The addition of a partial fundoplication has been demonstrated to reduce reflux¹²⁴ without impairing esophageal emptying.¹²⁵

A systematic review comparing the outcomes of 3086 patients who had laparoscopic myotomy to 1065 patients who had pneumatic dilation showed that symptom relief was significantly higher in the myotomy group at 12 and more than 36 months after treatment (89.3% vs. 68.2% and 89.3% vs. 56.3%, respectively).¹²⁶ However, in this study the myotomy outcome was compared with the result of the first pneumatic dilation, and the need for repeat pneumatic dilation was considered a failure. Currently, graded pneumatic dilation is considered as an accepted treatment approach.^{105,127} According to a Canadian study of 1181 patients initially treated with pneumatic dilation, the need for subsequent treatment, most often “touch up” dilation, at 1, 5, and 10 years was 36.8%, 56.2%, and 63.5%, respectively.¹²⁸ Recently, a multicentric European prospective trial randomized 200 achalasia patients to laparoscopic myotomy with Dor fundoplication or graded pneumatic dilation. After 2 years follow-up,

there was no statistical difference in success rates: 87% versus 92%, respectively.¹²⁹

Whereas laparoscopic myotomy with partial fundoplication and graded pneumatic dilation seem to be equally effective initial treatment options for achalasia patients, the choice of therapy should be guided by patients’ age, preference, and local institutional expertise.¹⁰⁵

Failure to reduce LES pressure may produce an “end-stage” dilated sigmoid esophagus, which may require esophagectomy.¹³⁰⁻¹³⁴ Although pneumatic dilation may be less effective in patients with megaesophagus, surgical myotomy may be a reasonable alternative before considering esophagectomy. Two studies showed 72% and 92% symptomatic improvement in this group of patients after myotomy.^{135,136} Despite treatment with pneumatic dilation or surgical myotomy, 10% to 15% will develop progressive deterioration of their esophageal function and up to 5% may eventually require an esophagectomy.¹³⁷ Esophagectomy is reserved for patients who fail pneumatic dilation and/or myotomy. Symptomatic improvement after esophagectomy can be expected in 80% with a mortality rate of up to 5.4%.¹³⁸⁻¹⁴⁰

Recently, a novel endoscopic myotomy technique has emerged as a minimally invasive alternative to the laparoscopic myotomy. The per-oral endoscopic myotomy (POEM) procedure was initially developed in Japan.¹⁴¹ Using a regular endoscope with a transparent cap, an endoluminal submucosal plane is created to gain access to the circular esophageal muscle for endoscopic myotomy with a dissection knife.¹⁴² The endoscopic myotomy is usually started 10 cm above and extended 2 cm below the gastroesophageal junction. The procedure time is approximately 2 hours. Short-term success rate of higher than 90% is reported in several studies.¹⁴²⁻¹⁴⁸ Symptomatic reflux and/or reflux esophagitis occurs frequently after POEM. POEM has been applied to all categories of achalasia, including end-stage disease, and to treatment failures from pneumatic dilation and laparoscopic myotomy. Nonrandomized comparison between POEM and laparoscopic myotomy indicate similar perioperative short-term outcomes.^{146,147,149} Wider use of POEM requires prospective randomized trials demonstrating the safety and long-term efficacy of this procedure compared with other effective treatment modalities for achalasia.^{105,150}

Hypercontractile and Spastic Disorders

Since the initial description of hypertensive and spastic motility disorders was realized with conventional manometry, substantial refinements and definition changes have been made with the invention and evolution of HRM.^{14,16,96,151-154} By analyzing esophageal contractile patterns in terms of esophageal pressure topography (EPT), rather than as line tracings, the conventional manometric criteria for hypercontractile and spastic disorders have changed significantly. Additionally, the EGJ morphology and dynamics can now be assessed in more detail for non-achalasia-related causes of EGJ outflow obstruction.^{155,156}

Diffuse (distal) esophageal spasm (DES) is a motility disorder of unknown etiology. The characteristic

pathophysiologic finding is impairment of deglutitive neural inhibition in the distal esophagus.¹⁵⁷⁻¹⁵⁹ Patients typically present with dysphagia and/or chest pain, and most patients have had extensive but negative cardiac evaluation for chest pain. Barium esophagram classically demonstrates a normal upper esophagus with a corkscrew or rosary bead pattern in the smooth muscle (distal two-thirds) portion (see Fig. 36-5A). DES is defined by manometric criteria rather than by clinical, functional, or pathologic criteria.⁹⁶ The diagnosis is therefore made by esophageal manometry. Traditionally, simultaneous contractions of normal (>30 mm Hg) or increased amplitude occurring after more than 20% of swallows were required for diagnosis, as was the presence of intermittent normal peristaltic contractions. Other findings that may be present are repetitive or prolonged contractions and elevated LES pressure.¹⁵¹ HRM has demonstrated that simultaneous contractions by traditional manometry are not true spasms; as a result, the conventional manometric definition may lead to overdiagnosis of DES, related to clinically irrelevant cases.^{96,160} DES was rare (1.5%) in a 400 consecutive patients study population.¹⁵⁴ The early Chicago classification interpreted “simultaneous contractions,” as described in conventional manometry schemes, as rapid contractions, defined by a contractile front velocity (CFV) greater than 8 mm/sec. DES was redefined by HRM as rapid contractions occurring with more than 20% of swallows.¹⁵⁴ The most recent Chicago classification proposed distal latency (DL) of less than 4.5 seconds (premature contractions) as an improved measure to represent simultaneous contractions.¹⁴ Reduced DL is thought to be indicative of a defect in distal neuromuscular inhibition.¹⁶¹ A recent study suggested that the diagnosis of DES based on an abnormal DL defines a more distinct clinical phenotype, whereas simultaneous contractions identify a large heterogeneous population, most of which do not have a clinical syndrome suggestive of esophageal spasm.¹⁶² Patients with premature contractions defined by a DL of less than 4.5 seconds were uniformly diagnosed clinically with a spastic disorder of the distal esophagus.¹⁶² The DL has therefore been adapted into the most recent Chicago classification to define DES.^{14,156,158,162} DES may progress to achalasia or be an atypical achalasia variant.^{158,163,164}

Because DES is poorly understood and there are most likely subgroups, including patients with predominant dysphagia or chest pain, multiple therapies have been tried with variable success.¹⁶⁵ Medical therapy includes PPIs, calcium channel blockers, nitrates, and sildenafil.¹⁶⁶⁻¹⁶⁹ Endoscopic therapy with botulinum toxin injection into the LES and the distal esophageal muscle has successfully controlled symptoms in selected patients.¹⁷⁰ Balloon or pneumatic dilation has been used for the subgroup of DES patients with poor relaxation of the LES.^{171,172}

An excellent review emphasizes the need for careful selection of patients for DES surgery and points out that surgery is rarely indicated.¹⁷³ For patients with severe DES refractory to medical therapy, a long myotomy extending from the aortic arch to the proximal stomach has been reported to provide good to excellent symptom control in 70%^{174,175} and to provide excellent medium-term control of dysphagia and chest pain.

However, 10% of patients have been reported to experience postoperative reflux.¹⁷⁶ Recent reports suggest that the recently developed endoscopic technique POEM might become an alternative treatment modality.^{177,178} Future studies are necessary to assess the efficacy of tailoring therapy for different DES subgroups.

Esophageal hypertensive peristaltic disorders, including nutcracker esophagus, spastic nutcracker or jackhammer esophagus, and hypertensive LES, represent a spectrum of abnormal esophageal vigor on esophageal manometry.^{14,152} Nutcracker esophagus is characterized by high-amplitude contractions of the distal esophagus (average peristaltic amplitude >180 mm Hg over pressure sensors 3 and 8 cm above LES by conventional manometry or as mean DCI >5000 and <8000 mm Hg/sec/cm by HRM), but esophageal peristalsis is normal. In 400 patient series, hypertensive peristalsis (mean DCI >5000 mm Hg/sec/cm) was found in 9% and nutcracker in 4% of patients.¹⁵⁴ By its definition, nutcracker can be seen in healthy volunteers and asymptomatic patients.^{95,154} Nutcracker has been reported in association with chest pain, dysphagia, and heartburn. It can be found in approximately up to 48% of patients with noncardiac chest pain undergoing esophageal manometry and in 10% with dysphagia.¹⁷⁹ Jackhammer esophagus (Fig.

FIGURE 36-19 ■ High-resolution manometry and traditional manometry in a patient with jackhammer esophagus show esophageal pressure topography and line tracings of a swallow with extreme distal contractile integral (DCI = 22,640) and multi-peaked contractions. Esophageal peristalsis and the esophago-gastric junction relaxation are normal.

36-19) refers to a hypercontractile disorder where at least one propagated swallow-induced contraction has a DCI greater than 8000 mm Hg/sec/cm by HRM in the context of normal EGJ relaxation. The contraction is usually multipeaked, associated with repetitive prolonged contractions evoking the action of the jackhammer.¹⁵² This disorder is rarely seen in asymptomatic subjects and is found in only 4% of manometries.¹⁵³ Most patients are symptomatic, most often with dysphagia and/or chest pain or reflux symptoms. The pathophysiology is largely unknown but patients with hypertensive contractions have been noted to have increased esophageal muscle thickness on endoscopic ultrasound.¹⁸⁰ Hypercontractile esophagus may be attributable not only to primary esophageal muscle hypercontractility but also secondary to reflux disease or mechanical obstruction at the gastroesophageal junction.^{152,153,181} Treatment is medical; however, it remains to be determined if medical treatment is associated with reduction of symptoms. GERD is often present, and these patients should be treated with a PPI. Calcium channel blockers have not been found to be consistently effective. Trazodone and imipramine reduced chest pain in some patients.¹⁶⁸ Botulinum toxin injection in esophageal muscle has also been used.¹⁸² Surgery should be avoided.

Hypomotility Disorders

Hypocontractile motility disorders are nonspecific esophageal motor abnormalities that are frequently encountered.¹⁸³ They have been classified as ineffective esophageal motility (IEM), mild to severe peristaltic dysfunction or, most recently, as weak peristalsis with small or large peristaltic defects (breaks) and/or frequent failed peristalsis.^{14,151,154,184} IEM is most frequently associated with GERD, especially erosive esophagitis, and can be found in over 30% of GERD patients. Hypotensive LES pressure is commonly observed in patients with severe GERD and a large hiatal hernia. Hypomotility is also observed in approximately 30% of patients presenting with nonobstructive dysphagia without GERD.¹⁸⁴⁻¹⁸⁶ Therapeutic options to restore contractility are limited, but patients with borderline esophageal motor function have a good long-term outcome.¹⁸¹ Empiric therapy with PPIs is a reasonable approach because of the frequent association of IEM with GERD. In patients with predominant dysphagia despite PPI treatment, empiric dilation can be done; however, this is controversial.¹⁸⁷

Absent peristalsis or severe hypomotility can cause dysphagia after complete fundoplication. The degree of hypomotility needed to result in post-fundoplication dysphagia is unclear; patients with complete aperistalsis (such as achalasia or scleroderma) will harbor a high prevalence of dysphagia. Patients who have preoperative dysphagia along with hypomotility are more likely to develop worsening dysphagia postoperatively.¹⁸⁸ Incomplete fundoplication should be considered in these patients. On the other hand, some patients with preoperative dysphagia and IEM may have improvement of the esophageal body function and/or the dysphagia postoperatively.^{188,189} Impedance manometry can assess which patients with IEM have abnormal bolus transport,¹⁹⁰ and,

as with standard manometry, HRM can assess the entire peristaltic wave-front rather than just three to four pressure sites. Few studies have related the risk of dysphagia after fundoplication using impedance manometry.¹⁸¹ One study showed that impedance manometry could not predict dysphagia in patients with GERD or its occurrence after laparoscopic Nissen fundoplication.¹⁸⁸ However, patients who had worsened postoperative dysphagia had preoperative lower liquid bolus clearance rates and longer liquid bolus transit times, compared with patients who did not have worsening of dysphagia.

Secondary Esophageal Motility Disorders

Scleroderma, or progressive systemic sclerosis, is a systemic disease that commonly results in esophageal dysfunction. Fibrosis, collagen deposition, and patchy smooth muscle atrophy are histologic hallmarks of esophageal involvement. The esophageal skeletal muscle is unaffected. Destruction of esophageal smooth muscle results in diminished or absent peristalsis of the lower esophagus and hypotensive LES in scleroderma esophagus (Fig. 36-20).¹⁹¹ Reflux and dysphagia are common complaints. Therapy includes aggressive acid suppression with potent PPIs and dilation of strictures.¹⁹² Surgery

FIGURE 36-20 ■ High-resolution manometry and traditional manometry in a patient with scleroderma. There is a complete absence of smooth muscle contraction in the distal 75% of the esophagus. However, there is preserved striated muscle contraction in proximal 25% of esophagus. Lower esophageal sphincter pressure is less than 5 mm Hg.

should be avoided if possible, especially if aperistalsis is present. When surgery is performed, it usually requires esophageal lengthening (Collis gastroplasty) and a partial fundoplication.¹⁹³ For extensive, repairable esophageal damage, resection may be required.

Neurologic and muscular disorders such as stroke, amyotrophic lateral sclerosis, and muscular dystrophies may be accompanied by esophageal dysfunction. Esophageal involvement is also seen in patients with diabetes or alcoholic neuropathy.

Diverticula

A diverticulum is an outpouching that protrudes from the gastrointestinal wall. True diverticula contain all layers of the gastrointestinal wall and are uncommon in the esophagus. Most esophageal diverticula consist of mucosa, submucosa, and strands of muscle fibers and are, therefore, false diverticula. The mechanisms by which diverticula develop are not completely understood. However, diverticula are categorized as pulsion, traction, or congenital, according to the suspected mechanism of formation. A pulsion diverticulum usually occurs at or proximal to an esophageal sphincter or proximal to areas of prolonged or increased pressure. They are assumed to be the result of excessive outward pressure on the gastrointestinal wall. Generally, these are false diverticula. Traction diverticula result from forces arising outside the gastrointestinal wall and are usually true diverticula. They are far less common and are found adjacent to regions of periesophageal inflammation, such as chronic lymphadenitis.

Diverticula of the esophagus are most commonly acquired. Pulsion diverticula can be located anywhere along the esophagus. Traction and congenital diverticula are rare. Focal diverticula occur in three common anatomic sites. Proximally, they occur in the hypopharyngeal or pharyngoesophageal region. Mid-esophageal diverticula are seen near the tracheal carina. Distal or epiphrenic diverticula appear within a few centimeters of the gastroesophageal junction.

Zenker Diverticulum

Zenker diverticulum is the most common esophageal diverticulum and occurs above the cricopharynx at the Killian triangle. Typically, it is located opposite the C6 or C7 vertebral body (Fig. 36-21). Incomplete UES opening is reported in patients with Zenker diverticula.¹⁹⁴ Over time, a permanent narrow-mouthed outpouching of the posterior pharynx and esophagus develops and enlarges inferiorly. As a result, saliva and ingested food-stuffs pool dependently in the sac and cannot empty easily into the esophagus.

Early on, patients may complain of a vague sensation or sticking in their throat, intermittent cough, excessive salivation, and intermittent solid food dysphagia. These minor symptoms may be dismissed as globus hystericus. As the sac enlarges, symptoms worsen as dysphagia becomes more frequent. This usually occurs in patients who are older than 50 years. Gurgling sounds during swallowing, regurgitation of undigested food ingested, halitosis, voice change, retrosternal pain, and respiratory

FIGURE 36-21 ■ Zenker diverticulum. Lateral view during barium esophagram shows a large diverticulum (A) that does not clear with repeated swallowing (B).

problems may be accompanying symptoms. To aid swallowing, patients use unusual maneuvers such as throat clearing, coughing, or placing manual pressure on the neck. In rare cases, the diverticulum can become large enough to obstruct the esophagus. A neck mass may be observed in these patients. The most serious complication associated with a Zenker diverticulum is aspiration, which can lead to pneumonia or lung abscess. Perforation, hemorrhage, or carcinoma may complicate Zenker diverticula.

A Zenker diverticulum is best identified and evaluated by barium esophagram, which can also evaluate the esophagus, as described earlier. Endoscopy is not required in all cases, but it is indicated when abnormal esophagram or concomitant esophageal or gastric symptoms exist. Experience is necessary to safely navigate past large diverticula. Manometric testing of the cricopharyngeal area is not clinically useful. Esophageal manometry is performed when symptoms or esophagram findings warrant it, and it usually requires endoscopic placement.

Treatment goals of Zenker diverticula are to increase UES compliance and reduce resting pressure in the cricopharynx. This can be accomplished endoscopically by creating an esophagodiverticulostomy with an endoscopic stapler.¹⁹⁵ Mid-term results with this technique are excellent.¹⁹⁶ Large diverticula and redundant mucosa are reported as risk factors for failure of endoscopic transoral stapling.¹⁹⁷ An open surgical myotomy is adequate treatment for small diverticula. For large diverticula, a myotomy with suspension or excision of the diverticulum is indicated.¹⁹⁸ Both endoscopic and open procedures provide similar outcomes with the same incidence of complications.¹⁹⁹⁻²⁰¹ The use of a traction suture to ensure complete incorporation of the diverticulum within the

stapler has been reported to reduce recurrent diverticula in patients undergoing endoscopic therapy.²⁰²

Midthoracic Diverticulum

Midthoracic diverticula usually develop within 4 cm to 5 cm of the tracheal carina. Until recently, these diverticula were commonly caused by traction secondary to mediastinal fibrosis and/or chronic lymphadenopathy from pulmonary tuberculosis or histoplasmosis. Many patients with these diverticula are found to have abnormal peristaltic waves from achalasia, DES, or other non-specific esophageal motor disorders (see Fig. 36-5B).^{203,204}

Patients with mid-esophageal diverticula may be asymptomatic; however, a history of dysphagia, retrosternal pain, regurgitation, belching, epigastric pain, heartburn, and weight loss may be elicited. Although attributed to the diverticulum, these symptoms may be the result of the associated motor disorder. Complications are unusual, but spontaneous rupture, hemorrhage, aspiration, esophagobronchial fistula, and carcinoma have been reported.

Most patients with midthoracic diverticula require no treatment. It has been reported that although 80% of patients had a proven motility disorder, only 20% required surgery.²⁰⁵ Diverticulectomy with esophageal myotomy is the preferred treatment for midthoracic diverticula associated with esophageal motility disorders. Right thoracotomy provides excellent exposure of the esophagus and airway at the tracheal bifurcation. Placing a bougie in the esophagus avoids compromise of the esophageal lumen and helps guide diverticulectomy. The mural defect should be repaired in two layers: the mucosal and submucosal layers closed with a continuous absorbable suture and the muscularis propria reapproximated with

interrupted absorbable sutures. The esophageal repair may be buttressed with pleura, pleuropericardial fat pad, or omentum. A myotomy can be carried out on the esophageal wall opposite the diverticulectomy. Diverticulectomy with suspension of the diverticulum superiorly from the prevertebral fascia,²⁰⁶ a myotomy alone,²⁰⁷ and diverticulectomy alone²⁰⁸ have been successfully applied in treating midthoracic esophageal diverticula. Treatment of true traction diverticulum, secondary to periesophageal inflammation, is often in the setting of an esophagobronchial fistula. Excision of the diverticulum, repair of the esophagus, removal of inflammatory nodes, closure of the airway fistula, and interposition of muscle are required.

Epiphrenic Diverticulum

Epiphrenic diverticula occur in the distal third of the esophagus, and the distal margin of the diverticulum is less than 4 cm from the gastroesophageal junction. There is usually an associated esophageal motor disorder or hiatal hernia.²⁰⁹ Epiphrenic diverticula may be asymptomatic, but patients typically present with dysphagia and regurgitation. They may also complain of vomiting, chest and epigastric pain, anorexia, weight loss, cough, halitosis, and/or noisy swallowing. There is no apparent relationship between symptoms and the size of the diverticulum. Symptoms may be attributable more to the underlying motility abnormality than to the diverticulum.

Barium esophagogram best identifies epiphrenic diverticula and often characterizes the underlying motility disorder (Fig. 36-22). Many patients show bizarre, nonpropulsive tertiary contractions during examination.

FIGURE 36-22 ■ Epiphrenic diverticulum. **A**, Barium esophagogram shows a large diverticulum. **B**, At esophagoscopy, the wide mouth diverticulum (upper arrow) and deviated distal esophageal lumen (lower arrow) are seen. Preferential filling of the diverticulum with swallowing can be appreciated from this examination.

In addition to fixed, wide-mouthed diverticula, transient outpouchings can occur proximally in segments where peristalsis is absent. Timed barium esophagogram may be used in any patient in whom an emptying disorder is suspected, particularly in patients with achalasia (see Fig. 36-7). Esophagoscopy generally yields little information about diverticula but may rule out malignancy and assess associated esophageal problems. Esophageal motility is essential before surgery. Esophagoscopy may be required to pass the manometry catheter past the diverticulum into the stomach.

Most authors agree that a diverticulectomy alone may result in a recurrence and advocate adding a myotomy.²¹⁰⁻²¹² Addition of an antireflux procedure to diverticulectomy and myotomy is controversial. However, if added, a partial (nonobstructing) wrap, such as a Belsey, Toupet, or Dor fundoplication, may minimize postoperative dysphagia.

Because epiphrenic diverticula are rare, most literature reports case series from single institutions. The optimal approach and the components of the operation remain controversial. A recent literature review of minimally invasive surgery for epiphrenic diverticulum identified 25 publications and 133 patients treated.²¹³ Most of these patients had both a myotomy (83%) and a fundoplication (85%). The operative mortality was 2%, morbidity was 21%, and 15% of complications were esophageal leaks.

Benign Esophageal Tumors and Cysts

Benign esophageal tumors are uncommon and represent less than 1% of esophageal neoplasms. EUS is essential in the diagnosis. Thus, classification by layer of origin in the esophageal wall is the most clinically useful categorization of benign esophageal tumors (Box 36-2).

BOX 36-2 Classification of Benign Esophageal Tumors

MUCOSA (FIRST AND SECOND ESOPHAGEAL ULTRASOUND [EUS] LAYERS)

- Squamous papilloma
- Fibrovascular polyp
- Retention cyst

SUBMUCOSA (THIRD EUS LAYER)

- Lipoma
- Fibroma
- Neurofibroma
- Granular cell tumor
- Hemangiomas
- Salivary gland-type tumor

MUSCULARIS PROPRIA (FOURTH EUS LAYER)

- Leiomyoma
- Duplication cyst

PERIESOPHAGEAL TISSUE (FIFTH EUS LAYER)

- Foregut cyst

Tumors of the Mucosa

Squamous papillomas are small (<1 cm), solitary, sessile projections in the distal esophagus and are usually found incidentally.^{214,215} They are uncommon, detected in 0.01% of 7618 esophagoscopies.²¹⁶ Histologic evaluation shows vascularized projections of the lamina propria covered by hyperplastic squamous epithelium. Biopsy differentiates squamous papillomas from small superficial squamous cell carcinomas. Because progression to malignancy is rare, asymptomatic patients require no follow-up. Symptomatic papillomas or those with atypical histologic features require excision, usually endoscopic. Although the cause of squamous papillomas is unknown, associations with human papillomavirus and GERD have been reported.^{215,217}

Fibrovascular polyps are collections of fibrous, vascular, and adipose tissue lined by normal squamous epithelium. Although fibrovascular polyps of the esophagus are uncommon in any one practice, the literature is replete with individual case reports. These polyps, which usually arise in the cervical esophagus and extend into the esophageal lumen, may reach into the stomach. Most patients complain of dysphagia and respiratory symptoms.²¹⁸ Regurgitation into the hypopharynx with subsequent aspiration and asphyxia is possible. These lesions can be detected by either barium esophagogram or esophagoscopy (Fig. 36-23). Because fibrovascular polyps fill the esophageal lumen and have a composition similar to that of the mucosa, diagnosis by esophagoscopy or EUS may be difficult or impossible.²¹⁹ Most polyps are surgically treated, although some have been removed endoscopically. Recurrence after resection is rare.²²⁰

Tumors of the Submucosa

At esophagoscopy, lipomas are noted as a bulging of the overlying esophageal mucosa. They have a pale yellow appearance and soft or pillow-like texture when probed endoscopically. Esophagoscopy biopsies demonstrate only normal squamous epithelium because forceps rarely penetrate the submucosa. EUS demonstrates a hyperechoic homogeneous lesion that originates in and is confined to the submucosal layer. If the patient is asymptomatic, only observation is required. Typically the lesions must reach an extremely large size before the patient becomes symptomatic. Rarely has malignant degeneration been reported.²²¹ Fibromas and neurofibromas are rare. At endoscopy, unlike lipomas, they are firm to the touch. These lesions, which arise from the submucosa, are less hyperechoic by EUS than are lipomas. Symptomatic submucosal tumors have been enucleated with minimally invasive techniques.²²²

Granular cell tumors are of neural origin and arise from Schwann cells. Most patients with granular cell tumors are asymptomatic and rarely require surgery.²²³ At esophagoscopy, these lesions are yellow, firm nodules, which can be diagnosed by routine endoscopic biopsies (Fig. 36-24). On EUS, granular cell tumors arise from the submucosa and are hyperechoic, but less so than lipomas.²²⁴ Nests of cells with pyknotic nuclei, abundant granular cytoplasm, absence of mitotic figures, and strong

FIGURE 36-23 ■ Fibrovascular polyp. **A**, A large polypoid filling defect of the intrathoracic esophagus is seen. **B** and **C**, Magnetic resonance image of tumor shows a large soft tissue mass filling the esophagus.

FIGURE 36-24 ■ Granular cell tumor. **A**, In a patient with dysphagia and acid reflux symptoms, barium esophagram shows a polypoid filling defect in distal esophagus. **B**, Esophagoscopy of another patient with a granular cell tumor shows a tumor that is extra-epithelial. Biopsy of this tumor was diagnostic for granular cell tumor.

S-100 protein expression characterize these tumors. Malignant variants have been reported.^{223,224}

Hemangiomas can present with dysphagia and bleeding. Most are found in the lower esophagus, where they may be mistaken for esophageal varices. EUS examination reveals a hypoechoic mass with sharp margins arising from the second or third EUS layer.^{225,226} Treatment options include observation, simple excision, fulguration, or radiotherapy.²²⁷ Salivary gland-type tumors have been rarely reported in the esophagus and probably arise from submucosal esophageal glands.

Tumors of the Muscularis Propria

Leiomyomas are benign smooth muscle tumors of the muscularis propria. They are the most common benign esophageal tumor and account for more than 70% of these neoplasms. Most arise from the inner circular muscle layer of the distal and midthoracic esophagus. There is no sex predominance. Leiomyomas typically occur in younger patients. Although frequently asymptomatic and discovered incidentally,²²⁸ leiomyomas can cause dysphagia, pain, or bleeding. In addition, distal

esophageal leiomyomas are often associated with symptoms of GERD. Barium esophagogram demonstrates smooth-contoured filling defects. At esophagoscopy and EUS, a normal overlying mucosa is seen over a hypoechoic tumor arising from the fourth ultrasound layer (Fig. 36-25). Atypical EUS findings are a tumor 4 cm or larger, irregular margins, mixed internal echo characteristics, and associated regional lymphadenopathy. Definitive diagnosis is difficult to obtain, because endoscopic biopsies do not reach the muscularis propria, and EUS-directed FNA does not provide enough information to differentiate leiomyomas from leiomyosarcomas.

Symptomatic neoplasms should be resected. For asymptomatic tumors with typical EUS features, expectant therapy and EUS observation are indicated. Leiomyosarcomas are exceedingly rare,²²⁹ and malignant transformation of benign leiomyomas has been infrequently reported.²³⁰ Gastrointestinal stromal tumors (GISTs) rarely occur in the esophagus and must be differentiated from leiomyomas. These tumors, which originate from the gastrointestinal pacemaker cells of Cajal, stain positively for tyrosine kinase and should be excised by esophagectomy.²³¹

Esophageal Cysts

Esophageal cysts are the second most common benign esophageal tumor, accounting for 20% of these lesions. The minority are acquired epithelial cysts, arising in the

lamina propria.²³² Submucosal glandular inflammation is the suspected cause. Most esophageal cysts are congenital foregut cysts.²³³ They are lined with squamous, respiratory, or columnar epithelium and may contain smooth muscle, cartilage, or fat. An esophageal duplication is a type of foregut cyst; it is lined with squamous epithelium, and its submucosal and muscularis elements interdigitate with the muscularis propria of the esophagus. Duplication cysts may be associated with vertebral and spinal cord abnormalities. Many patients with foregut cysts present in the first year of life with life-threatening respiratory compromise resulting from mass effect. EUS can clearly define the intramural or extraesophageal nature of these tumors and further determine their anechoic, cystic nature (Fig. 36-26).²³⁴⁻²³⁷ Regardless, removal of all discovered cysts is suggested because most become symptomatic by adulthood.²³⁸ In addition, trans-esophageal drainage has also been reported, but drainage of the cyst without destroying its lining often results in recurrence.²³⁹

Esophageal Injuries

Strictures

Various benign congenital and acquired disorders as well as malignant lesions can result in esophageal stricture. Congenital esophageal strictures, although rare, occur in the distal esophagus. They may result from the same

FIGURE 36-25 ■ An esophageal leiomyoma (L). *Top*: Esophageal ultrasound (EUS) of this most common benign tumor demonstrates a hypoechoic, homogeneous, well-demarcated tumor with no associated lymphadenopathy. EUS balloon overdistention blends the first three ultrasound layers into one hyperechoic layer. Tumor arises from and is confined to the fourth ultrasound layer (arrow). *Bottom*: A benign leiomyoma arises from and is confined to the muscularis propria.

FIGURE 36-26 ■ Foregut cyst. *Top*: Esophageal ultrasound demonstrates a mass (arrowheads) adjacent to the trachea and esophagus. The cyst has two components, one hyperechoic (white) representing proteinaceous material and one hypoechoic (black) representing fluid. *Bottom*: Foregut cyst in close proximity to esophagus and trachea.

developmental abnormalities that produce tracheoesophageal fistula or esophageal atresia.²⁴⁰ Acquired esophageal strictures can be benign or malignant (Box 36-3). Although most benign strictures result from chronic injury and resultant fibrous repair, they can occur after a single injury. Malignant strictures are usually primary esophageal adenocarcinomas or squamous cell carcinomas. Local invasion of a bronchogenic carcinoma or secondary involvement from breast, lung, or renal primary sites can produce a malignant stricture.

Causes of Esophageal Strictures

The patient typically does not perceive difficulty swallowing until the esophageal lumen is half its normal diameter. Because the obstruction is structural, dysphagia associated with esophageal stricture is unremitting and reproducible. Dysphagia from strictures can often be distinguished from other causes by history. Dysphagia in esophageal motility disorders is typically intermittent, with both liquids and solids. Chest pain is often present. Oropharyngeal dysphagia is suggested by choking, aspiration, drooling, or nasal regurgitation, in addition to a sense of solid bolus retention in the neck, resulting in repeated swallowing.

Barium esophagram is usually the first test in evaluation of dysphagia and suspected esophageal stricture. Subtle strictures may be found with a barium tablet (13 mm). Once the stricture anatomy is defined, esophagoscopy is crucial to characterize, biopsy, and dilate the stricture. EUS is an important diagnostic adjunct after successful dilation in strictures with submucosal or extrinsic features at esophagoscopy or esophagram.

A treatment algorithm for esophageal stricture is given in Figure 36-27. For benign dilatable strictures, the inciting agent must be identified and removed and the stricture treated by dilation as necessary. Simple benign strictures can usually be treated with bougie or through-the-scope balloon dilators. More complex strictures typically need wire-guided dilation, which is best done with fluoroscopy. Longer, more complex, and tight strictures are typically from corrosive ingestion, radiation, nasogastric tubes, eosinophilic esophagitis, or congenital esophageal stenosis; these are particularly challenging to dilate. Reported perforation rate is 0.1% to 0.4% and is seen mainly with complex strictures.²⁴¹ Frequent dilation may

be necessary, and stricture injection with steroids should be considered.^{242,243} Temporary stent placement has been increasingly used for refractory benign esophageal strictures, particularly plastic stents.²⁴¹ However, a recent pooled-data analysis on the use of self-expanding plastic stents for this indication suggested it was only moderately effective, with high early migration and complication rate.^{244,245} A recent preliminary study indicated that a biodegradable stent was safe and relatively effective for treating refractory benign strictures.²⁴⁶ Nondilatable benign strictures and resectable malignant strictures are treated by excision and reconstruction. Inoperable malignant strictures are palliated.

Peptic esophageal stricture is a late complication of severe, poorly controlled GERD and accounts for most benign esophageal strictures. Fortunately, peptic stricture is much less common since the widespread use of PPIs.²⁴⁷ Although initial damage is confined to the epithelium, with continued exposure to refluxed gastric contents, the injury progresses to involve the submucosa, the esophageal musculature, and, eventually, periesophageal tissue. The components of this injury are spasm, inflammation, and fibrosis. Eventually, the injury-repair cycle ends in cicatricial fibrosis and obstructive physiology of the distal esophagus. Most patients with peptic strictures present with dysphagia. It is less common for a patient to develop a symptomatic stricture during the treatment and follow-up of GERD. Although patients often do not have a prior diagnosis of GERD, more than 75% have symptoms of reflux.²⁴⁸

Most peptic strictures are located in the distal esophagus, usually above a hiatal hernia (see Figs. 36-4 and 36-6A). They are smooth, tapered areas of concentric narrowing. Occasionally, asymmetrical peptic scarring produces an eccentric stricture mimicking carcinoma. Symptomatic peptic strictures are usually 1 to 4 cm in length and 2 to 15 mm in diameter. They may be difficult to dilate, and they often recur, although aggressive PPI therapy makes this uncommon. Most peptic strictures occur at the squamocolumnar junction. Occurrence of the stricture well above the EGJ is suggestive of Barrett mucosa, which has been reported in 44% of patients with peptic esophageal strictures.²⁴⁹

Surgery should be considered for young patients who would require lifelong medication and for those who cannot tolerate medication. Early surgical correction provides better long-term results than late intervention, because the esophageal injury is more likely to be reversible.

Scleroderma should be suspected in patients with refractory and complicated GERD. The disease affects the smooth muscle of the esophagus and results in an incompetent LES and poor motility of the esophageal body. Massive reflux and insufficient esophageal clearance causes severe GERD and peptic complications that are difficult to treat. The mainstay of treatment is acid suppression and repeated dilation. Antireflux surgery should be avoided if possible because of poor or absent peristalsis. If required, an esophageal lengthening procedure and partial fundoplication are indicated. Total fundoplication may worsen the dysphagia because inadequate peristalsis and poor clearance may not overcome a

reconstructed LES. Peptic damage may be so severe that it requires resecting the amotile strictured esophagus.

Schatzki ring occurs precisely at the squamocolumnar junction (see Fig. 36-6B). These ringlike narrowings involve the mucosa and submucosa. They are thin, web-like constrictions, usually associated with small hiatal hernia, and are best seen radiographically. These rings may be missed at esophagoscopy because of incomplete distention of the esophagus. The most common symptom is intermittent solid food dysphagia when the internal ring diameter becomes 13 mm or less. Schatzki rings, thought to be reflux related, are amenable to dilation. Single large-bore bougie dilation may give long-lasting results, especially if PPI maintenance therapy is given after the dilation.²⁵⁰

Patients with pill-induced esophageal injury generally have no previous esophageal disease history. The initial injury is an ulcer, and patients typically present with chest pain and odynophagia.^{251,252} Then, painless dysphagia heralds the onset of a pill-induced stricture. Many patients recall the initial episode of pill lodging, typically a rushed ingestion done without caution, often without liquids and in a recumbent position. Pill injury is more common in women than in men.

Common locations of pill injury are in the cervical esophagus and the thoracic esophagus at the aortic arch, but other areas of anatomic or pathologic narrowing may trap a pill. Most medications produce superficial injuries that usually heal spontaneously. However, quinidine, potassium chloride, and Fosamax can produce severe esophagitis, and transmural injury may occur, leading to scarring and a stricture requiring dilation. Hemorrhage, mediastinitis, and free esophageal perforation have been reported.²⁵³

In rare cases, an esophageal stricture can be caused by a nasogastric tube in place for days to weeks. Patients develop symptoms weeks to months after tube removal. The mechanism of injury is unknown but is postulated to be trauma from tube insertion, chronic irritation by the tube, uncontrolled gastroesophageal reflux from an indwelling tube stenting the LES open, or impaired esophageal clearance secondary to the tube. Typically, barium esophagram demonstrates a long stricture with extensive ulceration in the mid and distal esophagus (Fig. 36-28). Initially, the strictures are smooth, tapered concentric narrowings that mimic peptic strictures. Progression can be rapid, with increased stricture length and severity resembling caustic strictures. Treatment includes dilation, avoidance of esophageal intubation, and aggressive antireflux medication.

Eosinophilic esophagitis (EE) has been recognized as a common cause of dysphagia and esophageal food bolus obstruction.²⁵⁴ EE is defined as a pathologic disorder characterized clinically by symptoms related to esophageal dysfunction and histologically by eosinophil-predominant esophageal inflammation (peak value of ≥ 15 eosinophils per high-power field) despite PPI treatment.²⁵⁵ Endoscopic findings suggestive of EE are multiple rings (corrugated rings or trachealization), linear furrowing, and a diffuse esophageal narrowing or narrow-caliber esophagus. Barium esophagram seems to be of low sensitivity to diagnose EE. Although EE can occur

FIGURE 36-28 ■ Nasogastric tube stricture. In a patient with prolonged intensive care unit stay and protracted period of nasogastric tube drainage, a barium esophagram 1 month after discharge demonstrates a long smooth benign-appearing stricture of the midthoracic esophagus.

at any age, it predominantly presents in childhood or during the third or fourth decade of life; it is more common in males than in females.²⁵⁶ Three main treatment modalities are used for EE, the three Ds: diet, drug therapy, and dilation.²⁵⁷ Whereas EE is believed to be an immune/antigen-mediated esophageal disease, particularly food allergy related, topical swallowed steroids are often recommended. Elimination diets have been particularly beneficial in children, but also in adult patients with EE.^{258,259} For persistent dysphagia related to fibrostenotic disease, esophageal dilation alone can result in long-lasting (>1 year) relief of the dysphagia in most patients.^{257,260,261} Recent studies have indicated that the esophageal perforation rate from dilation in EE is similar to that seen for esophageal dilation for other benign esophageal diseases.^{262,263} When a long tight stricture is present, multiple dilation sessions may be necessary, and a goal diameter of 14 to 15 mm is suggested.²⁶⁴

Radiation strictures can occur as early as 3 to 8 months after radiation dosages between 30 and 60 Gy.^{265,266} They are smooth, concentric, and tapered, and they lie in the radiation portals. Low-dose radiotherapy and concurrent doxorubicin administration can also produce esophageal strictures. Other esophageal complications attributed to these therapies include esophagotracheal and esophagobronchial fistulae.

Anastomotic strictures complicate as many as a third of reconstructions after esophagectomy. Factors that produce these strictures include anastomotic

tension, ischemia, infection, and radiation. Strictures are more common after anastomotic leaks, local infection, and adjuvant radiotherapy. Treatment is usually repeated dilation. Recurrent carcinoma may be difficult to detect by esophagoscopy and may require endoscopic ultrasound.^{267,268}

Corrosive Injuries

Corrosive injuries of the esophagus are caused by the ingestion of strong acid or alkali. There is a bimodal distribution of age and causes. In children younger than 5 years, ingestion is usually accidental—the result of an inquisitive toddler ingesting improperly stored corrosive agents. The first swallow of the noxious substance usually stops further ingestion and injury. In adults, ingestion of large volumes of caustic agents is usually a suicide attempt.²⁶⁹

Early Management. Obtaining a history of the estimated amount and nature of the ingested agent is critical to directing treatment.²⁷⁰ Bleach and phosphate detergents are irritants that rarely produce significant injury. Ingestion of strong acid produces coagulation necrosis, which may limit the depth of injury. However, rapid passage and pooling in the stomach can promote gastric injury.²⁷¹ Ingesting viscous alkali produces liquefaction necrosis and increases the depth of injury. Historically, most alkali agents were solids, generally restricting injuries to the mouth, oropharynx, hypopharynx, esophagus, and trachea. Significant solid corrosive ingestion may produce oral pain, drooling, excessive salivation, inability or refusal to swallow or drink, hoarseness, aphonia, dyspnea, stridor, and ulceration of the mouth, pharynx, or larynx. Currently, the availability of liquid alkali has altered the pattern of injury. These agents pass rapidly through the upper gastrointestinal tract, producing severe injury to the esophagus at physiologic points of narrowing (cricopharyngeus, upper thoracic esophagus at the tracheal bifurcation, and the distal thoracic esophagus) as well as to the stomach and adjacent intra-abdominal organs. Significant liquid caustic ingestion typically produces dysphagia, odynophagia, chest and abdominal pain, and signs of mediastinitis or peritonitis.

Patients should be admitted to the hospital and given orders not to receive anything by mouth. Because the injury is immediate, dilution or induction of emesis is not helpful. In fact, regurgitation of the alkali may worsen the injury by repeat exposure of the injured area to the agent. Fluid resuscitation and broad-spectrum antibiotic therapy are essential. Early administration of corticosteroids does not limit the depth of injury or reduce the incidence of late strictures.^{272,273} Intubation or tracheostomy and ventilation may be urgently required if there is significant laryngotracheal injury. Rapid evaluation of the upper gastrointestinal tract with flexible fiberoptic esophagogastroduodenoscopy is important to identify location and extent of injury. This is facilitated by the smallest esophagoscope available with limited use of insufflation. Grading of caustic injury is similar to that of cutaneous burns.²⁷⁴ First-degree injuries exhibit only mucosal edema and hyperemia. Second-degree injuries demonstrate

blisters with vesicle and pseudomembrane formation. Third-degree injuries produce deep ulcers with eschar formation.

Patients with first-degree injuries require no specific treatment; the incidence of stricture is low. Patients with second- and third-degree burns are at increased risk of early mortality and late complications. The esophagus should be allowed to reepithelialize; early dilation may increase stricture formation and risk for perforation.²⁷⁵ Frequent clinical assessment is necessary to detect and treat necrosis of the esophagus or stomach. Resection of the involved organ or organs with delayed reconstruction is recommended for transmural necrosis with mediastinitis or peritonitis. Tracheoesophageal fistula complicating caustic injury should be managed with esophageal resection and exclusion and tracheostomy.²⁷⁶ Reconstruction is delayed for several months. Patients without acute complications should be placed on a bland liquid or mechanical soft diet and prophylactic acid-suppression medication.

Ingestion of small alkali disc batteries presents a particular threat to small children. Severe esophageal injury may result within hours of ingestion, as a result of current generation, seepage of extremely corrosive contents from damaged cases, and pressure necrosis. Careful endoscopic removal is aimed at preserving the integrity of the battery case.²⁷⁷ Passage of batteries through the stomach or lower gastrointestinal tract is uneventful.

Late Management. Dilation of caustic strictures should begin a few weeks after injury if the patient is symptomatic or a stricture is demonstrated radiographically. Although retrograde dilation has been proposed as the safest dilation technique, it requires gastrostomy. Prograde guided bougienage or balloon dilation has been successful.²⁷⁸ Short strictures not responding to initial dilation may benefit from local steroid injection followed by repeat dilation.²⁷⁹ A biodegradable stent for palliation of dysphagia from caustic esophageal stricture has also been applied as an alternative new treatment modality.²⁸⁰ Axial shortening of the esophagus results in hiatal hernia and GERD and may worsen the original corrosive injury. Need for excessive dilation and inability to dilate to a sufficient diameter are indications for resection and reconstruction. Colonic interposition used to be preferred for replacement after resection of corrosive esophageal injuries, but the stomach, if not injured by the ingestion, is now the organ of choice.²⁸¹ Lye ingestion places patients at 1000 times the cancer risk of the general population.^{282,283}

Perforation

Perforation of the esophagus results in chemical and infectious mediastinitis, which is lethal unless treated early and effectively. Iatrogenic injury is the most common cause of perforation.²⁸¹ The incidence of this complication is less than 0.05% during diagnostic endoscopy, but it increases with the complexity of the procedure and the underlying esophageal pathology. A perforation rate up to 17% has been documented after dilation of caustic strictures and in approximately 2% (median rate, up to

16%) of patients with achalasia treated with pneumatic dilation.^{105,278,284,285} The esophagus may be injured not only by instrumentation but during any procedure performed in the vicinity of the esophagus. Trauma and spontaneous (barogenic) rupture are the next most common causes of perforation. The esophagus is normal in approximately 50% of perforations. Pathologic changes in the remaining cases include benign strictures in 25% of patients, diverticula in 15%, carcinoma in 10%, and achalasia in 5%.^{281,286}

A high index of suspicion is important for early recognition of injury. Symptoms of spontaneous rupture are often nonspecific and include acute chest and abdominal pain, odynophagia, dyspnea, and fever. A catastrophic presentation with acute sepsis may be seen. Any patient reporting symptoms after instrumentation of the esophagus should be considered to have a perforation until proved otherwise. Pleural effusion, pneumothorax, pneumomediastinum, and subcutaneous emphysema are nonspecific chest radiograph findings. However, chest radiographs are diagnostic in only 15% of patients and may be normal in 10%.²⁸⁷ Clinical diagnosis of esophageal perforation is confirmed by esophagram (Fig. 36-29). This is first performed with Gastrografin aqueous contrast material and, if that is negative, repeated with barium. Up to 22% of perforations are missed if only aqueous contrast is used.²⁸⁸ Computed tomographic scanning with ingestion of oral contrast has replaced barium esophagram in many institutions.

Some injuries may be contained within the wall of the esophagus. When the laceration is limited to the esophageal wall or when contrast material drains freely into the esophagus without distal esophageal obstruction, patients

FIGURE 36-29 ■ Perforation. Barium esophagram in a patient who has just undergone unguided esophageal dilation of a distal esophageal stricture shows extravasation of barium into the mediastinum.

without fever or elevated white blood cell count can be followed by observation.^{289,290} However, if a transmural injury with mediastinal soiling is identified, definitive management is required after fluid resuscitation and administration of intravenous antibiotics. The principles of surgical treatment are débridement of infected or necrotic tissue, closure of the perforation, treatment of underlying esophageal pathology (if present), and drainage of the mediastinum. A myotomy at the site of perforation allows the full extent of damage to the mucosa to be recognized and repaired. Reinforcement of the repair results in decreased mortality rate and decreased incidence of fistula formation.²⁹¹ Delayed recognition of a perforation makes successful primary repair less likely. Therapy should be directed toward defunctioning, débridement, drainage, and resection.²⁹²⁻²⁹⁴ Surgical drainage without repair is possible for most cervical perforations. Descending mediastinitis requires prompt treatment of the mediastinal component of a cervical perforation and may necessitate addition of a right thoracotomy to the cervical incision.²⁹⁵ Palliation of perforated esophageal carcinoma has been successful with self-expanding, covered metallic stents.²⁹⁶ One third of patients experience dysphagia after repair of esophageal perforations and require either dilation or further surgery.²⁹⁷ The best results are seen in patients with achalasia and other motor disorders who undergo a myotomy during perforation repair. In patients with strictures or diffuse esophageal disease, esophagectomy may produce the best long-term results.

Endoscopic stenting to obliterate perforations, preventing further soiling, has been rapidly accepted and is increasingly used.²⁹⁸⁻³⁰³ Ongoing drainage of the soiled area has been provided with percutaneous or minimally invasive approaches, obviating the need for open surgery.³⁰⁴ Esophageal stenting does not necessarily spare patients from undergoing additional surgical intervention for esophageal perforation, but it offers the advantages of esophageal salvage and earlier return to an oral diet. Esophageal stenting is likely to be unsuccessful in the cervical esophagus, at the EGJ, or in perforations longer than 6 cm.³⁰⁵

Multiple case reports and small series have used endoscopic clips to manage esophageal perforations. The inability to obtain durable, full-thickness closure has hindered their use. However, the newly introduced Over-the-Scope Clip has recently been reported to be highly successful in closure of esophageal perforations.^{306,307} Equally promising and extremely innovative is the use of intraluminal vacuum therapy.^{308,309} The apparatus is applied endoscopically and changed every 3 to 4 days until the perforation is closed.

Esophageal Foreign Bodies

Most ingested foreign bodies are seen in toddlers.³¹⁰ In younger adults, ingested foreign bodies are usually associated with drug or alcohol use or psychiatric illness. In older adults, with either dentures or esophageal pathology, a food bolus may be the impacted foreign body. Food bolus impaction is a common presentation in patients with EE and can lead to Boerhaave syndrome.^{311,312} The

site of impaction is invariably at a physiologic or pathologic area of narrowing. Plain film and contrast radiography are diagnostic for most patients. Most small blunt objects pass into the distal gastrointestinal tract without difficulty. Blunt impacted foreign bodies may be removed with a flexible esophagoscope and balloon catheters or baskets. Sharp or pointed objects, if the sharp edge is directed aborally, may be removed with flexible esophagoscopy; little damage is incurred from the sharp trailing edge. However, if the leading edge is sharp, rigid esophagoscopy with retraction of the sharp edge into the barrel of the rigid esophagoscope may be necessary. Surgical removal is rarely required for impacted foreign objects or those complicated by lacerations and mediastinitis.

CONCLUSION

The understanding of esophageal anatomy, function, and physiology is essential to correctly diagnose and successfully treat benign esophageal diseases. Except for hiatal hernia and GERD, esophageal conditions amenable to surgery are uncommon. Restoration of esophageal function and the ability to swallow are essential. It is imperative that the first operation be successful, or the patient is started down the path of multiple reoperations that will ultimately end in esophagectomy for benign disease.

MOLECULAR STAGING: PROGNOSTIC BIOMARKERS

SUMMARY

There were 17,460 estimated new cases of esophageal cancer diagnosed in the United States in 2012 and 15,070 estimated deaths.¹ The overall survival from esophageal cancer remains dismal at less than 17% at 5 years in the United States.² The poor prognosis can be attributed to advanced stage at diagnosis and biological characteristics of the cancer. Less than 50% of the patients will be eligible for potentially curative resection at time of presentation, but because cure is uncommon without surgical resection, the importance of complete staging of the patient to determine if he or she is a surgical candidate is in the patient's best interest. Eighty percent of the esophageal deaths in the United States are in men, and esophageal adenocarcinoma (EAC) continues to increase in incidence in non-Hispanic white men and women older than 55, whereas the incidence in African Americans is declining.

Although the prognosis of patients with EAC remains poor overall, there have been improvements in the 5-year overall survival rates for patients with local or regionally advanced disease. The prognosis for those with distant disease remains low at less than 3% at 5 years.² Improvements in staging modalities and appropriate selection of treatment for patients, as well as the endoscopic treatment of Barrett-associated superficial cancers, have contributed to the small improvement in survival. Significant advances have been made in less invasive therapeutic modalities from endoscopic mucosal resection (EMR) of in situ and intramucosal cancers to minimally invasive approaches for esophagogastrectomy. As the therapeutic management of esophageal cancer continues to evolve, EMR has joined the staging modalities for superficial lesions.³ Improvements in early detection of the disease,

selection of appropriate treatment for patients, and surgical approaches may eventually translate into improved overall survival rates. For superficial early T1a cancers, treatments with EMR, ablative therapy, and salvage esophagectomy have resulted in cure rates of 100%.⁴ For low-risk T1b tumors, 84% are without evidence of disease at a mean follow-up of 4 years.⁵ An esophagectomy provides the best chance of cure for a completely staged patient with esophageal cancer. Historically high perioperative mortality rates of 20% dissuaded many oncologists from referring patients for resection with curative intent.⁶ With modernization of approaches and improved perioperative care, the surgical mortality rates after esophagectomy have improved to less than 4%.⁷⁻⁹ Esophagectomy, however, should be considered a potentially curative option and not a palliative modality because of the negative impact on quality of life after such resection.¹⁰ There are more palliative options currently available in the form of stents, laser, and cryotherapy,¹¹ and resection may be reserved for the significantly bleeding or complicated perforated tumor. Accurate staging is also important for determining the best mode of palliation for stage IV patients and for carrying out a realistic discussion with the patient and family.

In addition to early detection of this disease, identification of early-stage patients with accurate staging tests allows optimal selection of surgical candidates. Routine noninvasive preoperative staging modalities available at most institutions include endoscopic ultrasound (EUS) and positron emission tomography–computed tomography (PET-CT) scans. Early-stage patients benefit from endoscopic or surgical resection, whereas

advanced-stage patients benefit from palliative procedures like ablation, dilation, stents, chemotherapy, or radiation to improve quality of life. Intermediate-stage patients can benefit from neoadjuvant therapy followed by restaging and surgical resection with curative intent.

Although clinical trials of neoadjuvant chemotherapy or chemoradiation previously have not shown a consistent survival benefit,¹²⁻¹⁵ a few recent individual studies and a meta-analysis have shown some benefit.¹⁶⁻¹⁹ With the completion of the ChemoRadiotherapy for Oesophageal cancer followed by Surgery Study (CROSS), however, neoadjuvant chemoradiation has become the standard of care at most centers for patients with clinical stage T3 or node-positive (cT3 or cN1/2/3) esophageal squamous carcinoma or adenocarcinoma.²⁰ Although this study included T2N0 cancers, the role of neoadjuvant therapy for such patients remains controversial.

This chapter will outline what is available now for staging the patient with endoscopic confirmation of a thoracic esophageal cancer.

ESOPHAGEAL CANCER TNM STAGING

The current staging system for esophageal cancer follows the American Joint Committee on Cancer (AJCC) *Cancer Staging Manual*, 7th edition, which uses the TNM system of T for tumor, N for regional nodal status, and M for presence or absence of distant metastases (Table 37-1).²¹ The TNM staging system was recently revised, and significant changes included modifying the T stage, incorporating the grade of the tumor into the stage, subdividing the N stage based on the number of involved lymph nodes, and separating adenocarcinoma from squamous cell carcinoma (SCC). There is also only one class for metastatic lesions. M1a and M1b, separating distant nodal and distant organ metastases, have been removed. High-grade dysplasia is now T in situ (Tis), and T4 has been divided into T4a and T4b. T4a cancers are locally invasive but are still deemed potentially resectable albeit with a portion of pericardium, pleura, or diaphragm. T4b tumors invade the trachea, aorta, or vertebral bodies and deem the tumors unresectable.

Another major modification in the staging system is the subset of nodal stage. As has been modified for gastric, colon, melanoma, and other malignancies, the number of lymph nodes involved has become a prognostic marker and thus incorporated into the formal staging system. Accurate clinical nodal staging of esophageal cancer is challenging, and typically the patient is clinically staged as either node-positive or node-negative; however, this change in nodal staging is an important prognostic adaptation. Multiple studies from different esophageal groups have found significant survival differences based on absolute number of positive lymph nodes,²²⁻²⁶ absolute number of negative lymph nodes,²⁷ and ratio of positive to negative lymph nodes.^{25,28,29}

The grade of the tumor is also now a part of the staging classification as poorer differentiation corresponds with worse prognosis.³⁰ T1 is divided into T1a for intramucosal cancers and T1b for submucosal lesions. This T stage modification is based on the incidence of

lymph node involvement and subsequent survival differences for tumors of increasing depth. Other changes include the addition of tumor location to the SCC staging and the staging of tumors of mixed histology as per the SCC group.

ENDOSCOPIC ULTRASONOGRAPHY

EUS staging of esophageal cancers was first advanced in the literature by Lightdale in 1992,³¹ and in the next decade the modality became a standard part of staging newly diagnosed esophageal cancer patients.³² Before EUS, CT scan was the primary modality available to decide whether to proceed with an esophagectomy on an otherwise medically fit patient presenting with esophagus cancer, although MRI and bone scans were sometimes indicated by clinical presentation. Now EUS is available to help determine locoregional stage of esophagus cancer as well as distant disease by providing cytology of liver and adrenal or celiac lymph node metastases.

For patients without evidence of distant disease on PET-CT, EUS is used for T and N stages to allow referral for neoadjuvant therapy. It is most often performed by the gastroenterologists; however, some surgical groups are experienced and it would behoove thoracic surgeons to be proficient so that they can offer one-stop shopping for staging esophageal and lung cancer patients.³³

Conventional EUS is carried out with conscious sedation using the 360-degree radial mechanical echoendoscope with a 7.5-MHz ultrasound probe. Conventional radial EUS is the best approach for assessing depth of primary tumor into the esophageal wall. For EUS-guided fine-needle aspiration (FNA) of suspicious lymph nodes, a curved linear array echoendoscope is used with a 22- or 25-gauge needle. A 7.5-MHz or lower frequency endoscope is better than the high frequency endoscope for assessing regional lymph nodes because of the greater depth of visualization. Endoscopic criteria for potentially malignant lymph nodes include at least two of the following characteristics: round, discrete, hypoechoic, or a dimension greater than 1 cm.^{34,35} EUS imaging of nodes alone is not specific enough, but FNA of the suspicious nodes can result in a specificity rate of up to 95%.³⁶

EUS remains the most accurate modality for determining T stage with accuracy rates ranging from 64% to 80% for the low-frequency probe³⁷⁻⁴⁰ and up to 85% to 92% for the high-frequency probe.^{35,38,41} Accuracy can only be calculated when patients have undergone histologic confirmation of their tumor and nodal status. The accuracy of EUS for staging of T and N in the most recent series of patients in the past 15 years is summarized in Table 37-2. As summarized, EUS staging is indicated before initiation of neoadjuvant therapy.

EUS has an accuracy range of 80% to 90% for T3 and T4 stages^{38,39} but for T1 and T2 the rate drops to 74%.³⁹ In a large series of more than 200 patients with pathologic confirmation of their tumor and nodal stages, most EUS staging errors were understaging of T0 and T1 and overstaging of T2.⁴² The reliability of EUS for accurately staging T2N0 tumors was examined by Crabtree and colleagues, who retrospectively studied the Society of

SCC, Squamous cell carcinoma.

Thoracic Surgeons (STS) General Thoracic Surgery Database (GTDB) and concluded that clinical staging of T2N0 tumors is unreliable.⁴³ They reported a 26% downstaging and 47% upstaging of clinical T2N0 (cT2N0) patients treated with primary esophagectomy. EUS accurately staged T3 and T4 lesions in 85% of cases.³⁷ In another series, of 47 patients undergoing surgical resection for adenocarcinoma or SCC, EUS overstaged T stage in 19% of patients and understaged it in 17%.⁴⁴

In studies with pathologic confirmation, the accuracy rates for N stage range from 70% to 86%.^{34,37-39,45} Before FNA-guided biopsies of lymph nodes by EUS was applied, the false-negative rate of EUS for nodal stage exceeded 33%.⁴⁶ Endobronchial ultrasound (EBUS) has also been combined with EUS to improve the staging

precision of ultrasound modalities. As demonstrated in a prospective clinical trial (NCT01038544), patients with newly diagnosed esophageal cancer underwent radial and convex EUS followed by convex EBUS to evaluate the standard nodal stations.⁴⁷ EBUS complemented the examination of stations 2, 4, and 7 by EUS but also provided access to lymph node level 10R. EBUS added to the sensitivity of the EUS by upstaging 12% of the patients and contributing to the EUS stage in 69% of the patients. The EBUS scope also could be passed across tight malignant strictures, which precluded staging with the EUS but allowed for a clinical T and N stage of tumors that could not otherwise have been staged.

Although EUS has added much to the clinical staging and management of esophageal cancer patients, it still is limited by malignant stenoses preventing staging of the

primary tumor. In these cases, however, tumor obstruction almost always represents T3 or T4Nx.⁴⁵ In addition, the probability of a T3 or T4 tumor being N1 exceeds 80%.⁴⁸

With the continued expansion of endoscopic therapy for patients with early esophageal cancers, accurate staging of T1 adenocarcinoma with EUS will be important to determine which patients may be offered endoscopic therapy with potential cure and which patients should undergo esophagectomy. From *experienced* EUS groups, the accuracy of staging an intramucosal (T1a) cancer was 82% to 94%.^{34,38,49} A T1b cancer has about a 20% likelihood of lymph node metastases versus the intramucosal lesion, which is less than 5%; thus, the EUS T stage may help in choosing between endoscopic and surgical resection.⁵⁰ EUS before endoscopic resection of T1 tumors remains controversial, however, because it is not highly accurate and the patient should probably just have the EMR for staging the superficial lesion.

For the patient initially presenting with a localized cancer, conventional EUS with a 7.5- to 12-MHz radial ultrasound probe is good for initial assessment of tumor infiltration and looking for suspicious lymph nodes (hypoechoic, >1 cm). The higher frequency 12- to 20-MHz probe may provide the most accurate staging for the T1 or T2 suspicious tumors,⁴³ but generally with EUS, pT1 tumors are understaged by 18% and pT2 tumors are overstaged by 47%.⁴⁰ The exam should include a full evaluation of the liver and lymph nodes in the paragastric, subhepatic, and celiac stations. If a suspicious node is identified, a curvilinear echoendoscope allows FNA of the suspicious node.

EUS and Neoadjuvant Therapy

Although EUS is feasible in 70% of patients after neoadjuvant chemoradiation,⁵¹ its accuracy rate with current neoadjuvant modalities drops below 50%.^{35,52} It over-stages the tumor depth in more than 49% of cases and over-stages the nodal status in more than 38% of cases.⁵³ The accuracy for T stage after chemoradiation at current radiation doses of 45 Gy ranges from 37% to 43%.^{35,52} Radiation fibrosis causes overstaging or understaging of T stage about 40% of the time^{51,54} because of radiation fibrosis. T stage by EUS after chemotherapy may be accurate only when the tumors don't respond to the chemotherapy.³⁵ EUS essentially is not recommended after neoadjuvant chemotherapy or chemoradiation because of the low accuracy rate⁵² secondary to the postinflammatory changes.^{35,55} Post-chemoradiation CT scan or endoscopy alone, however, is not as good as EUS in assessing treatment response.⁵⁸

Metastatic Disease

EUS is useful for confirming metastases to celiac lymph nodes (CLNs), which portend a worse prognosis.⁵⁷ CLNs were evaluated in 95% of 62 patients in Reed's series from 1999. In this group, EUS sensitivity was 72% and specificity 97%.⁵⁸ The presence of CLN metastases as detected by EUS has also been associated with a worse survival for all T stages. In another study, from Medical University of South Carolina, the authors concluded the 5-year survival rate of patients without celiac nodal involvement, as detected by EUS, was three times better than patients with CLN involvement (39.8 versus 13.8 months).⁵⁹ EUS can also be helpful in obtaining and evaluating biopsy of liver metastases.⁶⁰ In a recent study of 132 patients, EUS-FNA on noncystic liver lesions confirmed liver metastases in 20% of the cases and EUS was superior to CT in quantifying liver metastases, especially in cases where the metastases were too small to be characterized by CT scan.⁶⁰

ENDOSCOPIC MUCOSAL RESECTION

Aside from the number of involved lymph nodes and the grade of the primary esophageal tumor in the new TNM staging system, the subclassification of T1 into T1a and T1b reflects the acceptance of EMR for diagnosis, staging, and treatment of superficial esophageal cancers. The pioneers of this technique for superficial EACs, May and colleagues, initially reported that in 50 patients, endoscopic resection was a therapeutic alternative to esophagectomy for high-grade dysplasia (now known as Tis) and early adenocarcinomas in patients with Barrett esophagus.⁶¹ The technique was adapted from the Japanese approach to treating superficial gastric cancers and essentially involves identifying the mucosal abnormality and either cutting and coagulating it or using a suction, banding, and ligating method as one might use for a polypectomy. For EMR, the depth of resection is the submucosa. If the muscularis propria is involved, the EMR cannot be completed, at least not with the suction

banding technique. After the lesion is removed, it is carefully oriented by the operator and fixed and examined by a gastroenterology pathologist to classify it as a Tis, T1a, or T1b tumor. There are more specific depth classifications for T1b lesions depending on the level of involvement of the submucosa. Submucosal (sm) 1-3 categorization correlates with frequency of nodal involvement^{5,62}; however, T1b substaging is not part of the seventh edition of TNM staging. The risk of occult nodal involvement in T1a tumors is considered very low, ranging from 0% to 7% in 79 esophagectomy patients.⁶³⁻⁶⁵ Any potential for lymph node involvement dissuades some surgeons from recommending endoscopic therapy except when patients are at high surgical risk.^{63,64} Grade of tumor and lymphovascular invasion are established negative prognostic markers. In future validation studies, molecular staging of the primary tumor will help surgeons decide which patients need an esophagectomy and which can be treated endoscopically.

For T1b tumors, nodal involvement increases significantly, ranging from 21% to 50%⁶⁵; thus surgical resection is indicated. The addition of this modality has significantly and safely impacted the management of patients with mucosal esophageal cancers, who can then be spared a potentially morbid esophagectomy.⁴

COMPUTED TOMOGRAPHY

Accuracy rates of CT scanning for assessing depth of esophageal cancer and gastroesophageal junction (GEJ) cancer are notoriously poor, ranging from 33% for T2, 0% for T3, and 50% for T4 for an overall rate of 15%, and CT tends to understage tumor depth.⁶⁶ Although in more recent series the overall accuracy of CT for T stage was 59%,^{38,46,66,67} CT is used more for identifying distant metastases and suspicious regional nodes than for assessing tumor depth. Historically, nodal staging by CT averaged 50% for node-positive patients,⁶⁶ and the combination of EUS and CT for detecting regional nodal involvement accurately was 82% in a series of 42 patients undergoing surgical resection.⁴⁸ The sensitivity of CT staging of CLNs was only 8% in slightly older series, although the specificity was 100%,⁵⁸ but only 64% accurate for diagnosing stage IV disease by solid organ metastases or distant lymph node metastases in 74 Belgian patients.⁴⁴

Routine CT scans have improved the detection of distant metastases, but they have generally been replaced by the more sensitive PET-CT. Certainly it remains common for patients to have a staging CT scan of the chest and abdomen before they are referred to the surgeon for evaluation. CT scan may still have a role in evaluating chemoradiation response, however. Some groups have suggested that a reduction in maximal cross-sectional area of the tumor on CT scan may be helpful in assessing chemoradiation response preoperatively.^{52,68} Similarly, earlier studies suggested that preoperative CT width of the cancer may be a prognostic factor⁵⁶ even without neoadjuvant downstaging.⁶⁹ This staging of tumor measurements on radiographics is developing new interest with assessment of treatment response based on tumor length.⁷⁰

POSITRON EMISSION TOMOGRAPHY—COMPUTED TOMOGRAPHY

Just as EUS contributes to the preoperative evaluation and management of patients newly diagnosed with esophagus cancer, PET-CT adds biological information about the primary tumor and is standard for identifying distant disease.

Before the wider availability of PET-CT, the usefulness of PET alone was investigated for staging esophagus cancer patients. Flanagan et al at Washington University found that in 29 patients who underwent curative surgery (19 with adenocarcinoma), PET scan accurately detected regional nodal disease in 76% of patients and distant metastases in 93% of the patients. PET identified regional nodal involvement twice as often as CT in 21 patients undergoing esophagectomy for adenocarcinoma or SCC and improved detection of metastatic disease by 80% (45% by CT and 82% by PET-CT).⁷¹ For detecting stage IV disease in patients with EAC or SCC, PET alone had sensitivity, specificity, and accuracy rates of 74%, 90%, and 82% when compared with rates of 41%, 83%, and 64%, respectively, for CT scan.⁴⁴ Small (<1 cm) hepatic metastases were missed by both PET and CT scan in one patient, and in another patient a pancreatic metastasis was missed.⁷² The authors concluded that PET changed clinical management in 17% of 36 patients with adenocarcinoma or SCC.⁷² False-positive results on PET alone can result from granulomatous disease, reactive hyperplasia, or local extension of tumor misinterpreted as regional nodal involvement.^{44,72} False-negative regional lymph node involvement can result from occult, micrometastatic disease in normal-sized nodes and in nodes adjacent to the primary tumor where the PET uptake of the primary tumor obscures the nodal uptake. False-negative findings of stage IV disease by PET can result from peritoneal metastases, small (<1 cm) or superficial hepatic metastases, and small lung lesions.⁴⁴

Results of the ACOSOG Z0060 trial of PET staging in esophagus cancer were published in 2007.⁷³ In this intergroup trial, PET alone and not PET-CT was used to determine whether PET could improve on an acceptable 5% rate of metastasis detection and hence prevent unnecessary surgery for esophageal cancer patients with metastatic disease. All patients underwent a CT of chest and abdomen first; then, if that was negative, they had a PET scan to look for stage IV disease. Although tissue confirmation of PET-positive, suspicious lesions was part of the study algorithm, not all patients were able to undergo confirmatory biopsies of PET-positive areas. Indeed two patients who underwent procedures sustained complications after biopsy or after an adrenalectomy, procedures performed based on a false-positive PET result. Of the 145 patients who had a PET scan negative for metastases and who underwent potentially surgical resection, 5.6% developed recurrent cancer (location not otherwise specified) within 6 months of surgery. The group concluded that confirmed metastatic disease was detected in 4.8% of patients otherwise potentially eligible for curative surgery after body CT staging and as needed brain or bone imaging and that tissue confirmation is

important for avoiding the 3.7% false-positive rate resulting from PET scanning of these patients.

Initial Staging

With the advent of PET-CT more than 15 years ago,^{44,74,75} this modality has replaced PET alone at most institutions. One of the big advantages of PET scan over CT scan alone is the three-dimensional imaging with PET. This modality also identifies second primary tumors more than CT scans.⁷¹ PET is not used to diagnose esophageal cancer but instead to evaluate regional nodal disease and distant metastases. Lymph node status is the most important prognostic predictor for patients with potentially resectable disease,⁷⁶ and clinical staging of positive lymph nodes triages the patient to induction therapy. Ideally the patient should have histologic confirmation of PET-positive nodes before neoadjuvant therapy is initiated, but such stringent management is not routine.

The minimum lesion size that can be detected with PET scan alone is 5 mm.⁷⁷ PET-CT improves the accuracy of PET alone for identifying malignant lymph nodes, as demonstrated in a series of 39 patients, because the CT improved the localization of the PET tracer.⁷⁸ In this particular study, small lymph nodes (6 to 11 mm) that were negative on PET were detected with PET-CT. PET findings for detecting or eliminating metastatic disease have been shown to change patient management in about 20% of patients staged by CT initially.⁷⁷ PET alone is very sensitive for the primary tumor being hypermetabolic in more than 95% of cases.^{44,71,79}

The PET-CT is carried out in similar fashion to PET with the patient fasting for at least 4 hours before scan so that they are normoglycemic at time of the study. The radiopharmaceutical is ¹⁸F-2-fluoro-2-deoxy-D-glucose (¹⁸F-FDG), the tracer for glucose metabolism. ¹⁸F-FDG is taken up into the cell and phosphorylated but cannot be metabolized as glucose-6-phosphate and instead is trapped within cells using high rates of glucose. The patient receives the ¹⁸F-FDG, then a CT scan followed by the capture of the PET images within 45-60 minutes of injection of the radiotracer. The PET and CT images are fused and both PET and PET-CT images are analyzed. The accuracy of lymph node staging in EAC has increased from 78% with PET alone to 83% with fused PET-CT.⁷⁸ The authors of this study found the staging accuracy increased to 95% when they included the diameter of the primary tumor. In a meta-analysis of 12 studies, PET-CT had a sensitivity and specificity of 55% to 62% and 76% to 96%, respectively, for nodal staging; however, the authors concluded that the accuracy was no better than PET alone.⁸⁰ Manabe and colleagues supported some of these findings when they found that PET-CT has a sensitivity range of 29% to 53% for nodal metastases in thoracic SCCs, but the specificity of the study was 90% in regional thoracic nodes.⁸¹ They also found that, as is seen for some primary lung cancers, a low standard uptake value (SUV) of the primary tumor correlated with limited detection of nodal metastases because of low avidity for the radiopharmaceutical tracer.

PET-CT is the standard test for detecting stage IV disease. In a diagnostic imaging study from M. D.

Anderson Cancer Center, PET-CT was used to detect distant metastases in 22% of esophageal cancer patients undergoing initial staging.⁸² The most common sites of metastases were liver (10%), bone (9%), lung (9%), adrenal glands (2%), and peritoneum (1.4%). In addition, "atypical" metastases were found in the skeletal muscle, brain, and thyroid in 0.3% to 1.7% of the patients. One patient (0.5%) was found to have a synchronous colon cancer after colonoscopy for focal uptake by PET-CT. Although some authors have suggested it is not ethically possible to always confirm histologically metastatic disease,⁷⁷ the counterargument is that it is ethically right to proceed with a biopsy if possible and if potentially curative options are available.

Patients who respond to chemotherapy or chemoradiation therapy have a better prognosis after surgical resection,^{13,15,83-86} and some groups have suggested only the complete responders have survival benefit.⁸⁷ Complete pathologic response occurs in approximately 25% of cases.^{79,88}

Interval Staging

What is the role of a PET scan in assessing response to the neoadjuvant treatment? Historically an interval PET or PET-CT scan was done after two cycles of chemotherapy⁸⁸ to select out the responders and the nonresponders. The Metabolic response evaluation for Individualization of neoadjuvant Chemotherapy in esophageal and esophagogastric adenocarcinoma (MUNICON) I and II trials investigated locally advanced distal esophageal and GEJ adenocarcinomas, in which interval metabolic response evaluation was used to classify patients as nonresponders or responders.^{89,90} In the MUNICON I trial, responders were deemed those who had a greater than 35% decrease in the SUV of the primary tumor after 2 weeks of induction chemotherapy. Nonresponders went to surgery and had a worse median overall survival of 25.8 months compared with the responders, who received a complete course of neoadjuvant chemotherapy. In MUNICON II, PET nonresponders received neoadjuvant chemoradiation resulting in an increased histopathologic response but still with a significantly lower 2-year overall survival.⁹⁰ As based on the MUNICON II trial,⁹¹ this approach is helpful for patients treated with neoadjuvant chemotherapy.

Because the standard of care, since the CROSS trial particularly, has become neoadjuvant concurrent chemoradiation, interval staging with PET-CT is not feasible. In MUNICON II, Lordick summarized that interval staging is less common as most patients are treated with neoadjuvant chemoradiation and the radiation can show misleading persistently positive disease with little response.

Restaging

A metabolic response by PET or PET-CT scan is increasingly being shown to correlate with histologic response to induction therapy with a sensitivity of 89%.^{91,92} In one study of 37 patients with GEJ adenocarcinomas (98% clinical stage T3Nx, 2% T4Nx), those with a significant

decrease in SUV also were able to undergo complete surgical resection.⁹¹ In addition, a significant decrease from maximum SUV on repeat PET images after induction therapy predicts a lower likelihood of disease recurrence⁹¹ and improved disease-free and overall survival.^{79,91-94} The optimal timing of the repeat PET-CT after neoadjuvant chemotherapy or chemoradiation therapy is typically 3 to 4 weeks after completion of treatment. Metastatic disease is identified in 8% to 17% in posttreatment PET-CT.^{79,88,95} Additional distant metastases can be found intraoperatively, in an additional 2% to 6% of patients,^{79,88} and in one series 29% of patients had pathologic N1 nodes despite a negative PET-CT before esophagectomy.⁸⁸

An interesting aspect of restaging with PET-CT scans is the potential prognostic information from the decrease in SUV as was suggested initially by Downey et al, who stratified 17 patients after induction therapy into those with a greater or less than 60% change in SUV pre- and post-chemoradiation.⁹³ Of the eight surgically resected patients who had a greater than 60% decrease in SUV peritreatment, 67% were disease-free at 2 years postoperatively. The 2-year overall survival rate difference was 89% versus 63% for the two groups with the 60% SUV cutoff. Other studies support using a relative decrease in SUV as a predictor of histologic response to induction chemotherapy, and the sensitivity from Roedl et al was 86% for identifying responders.⁷⁰ The correlation of change in primary tumor SUV and histologic response to chemoradiation is controversial though.^{79,88} In a set of 55 patients who underwent esophagectomy, PET-CT had only a 39% positive predictive value for differentiating patients with a pathologic response.⁸⁸ In another study the positive predictive value of PET for determining pathologic complete response was only 50%.⁷⁹ The optimal cutoff point of what is considered significant is not known. Some groups use higher than 35% for a sensitivity and specificity of 75%, and a greater than 45% decrease in SUV for a specificity of 86%,⁹¹ while greater than 60% was used for predicting improved survival. Finally, the Massachusetts General group concluded in their 47 patients with esophageal or GEJ cancers that decrease in tumor length as assessed by PET-CT was a better predictor of treatment response than was change in SUV.⁷⁰

The standard interval for the restaging PET-CT after completion of neoadjuvant chemotherapy or chemoradiation therapy is about 21 to 40 days.^{79,88} At most institutions it is not yet standard to forego an esophagectomy in patients without a significant decrease in SUV of the primary tumor.⁸⁸ Although it is not the standard to repeat the EUS, the M. D. Anderson group gave it a positive predictive value of 88% for evaluating tumor response to neoadjuvant therapy.⁸⁸ Also they have found that adding PET-CT to a postinduction repeat endoscopy improved significantly the ability to detect residual tumor compared with repeat endoscopy alone.⁹⁶

Although change in SUV on pretreatment and posttreatment PET-CT has prognostic significance, the primary role for the postinduction PET-CT is to rule out metastatic disease that would preclude the patient from benefitting from a surgical resection.

SURGICAL STAGING

What is the role of staging the newly diagnosed esophageal cancer patient surgically? That question was examined by a few groups and then the feasibility evaluated in a multicenter trial led by Krasna.⁹⁷ Early results of surgical staging for esophageal cancer entered the literature in 1995, when Krasna et al reported the CALGB pilot study findings of video-assisted thoracoscopic surgery (VATS) staging.^{98,99} The three institutions involved concluded that VATS staging of patients with thoracic esophageal cancer was feasible in 95% of patients enrolled and that 88% of the patients undergoing esophagectomy with confirmatory pathologic stage were correctly staged. Then Luketich et al and Bonavina et al separately reported the use of laparoscopy.^{100,101} In the study by Bonavina and colleagues, 50 patients with distal EAC or SCC underwent CT scan, EUS, and laparoscopy. The investigators concluded that laparoscopy was safe, was quick (mean time 20 minutes), and changed the therapeutic approach in 10% of patients.¹⁰¹ Luketich and colleagues at the same time published results of minimally invasive staging of 26 patients with EAC (92%) or SCC and compared laparoscopic/right VATS staging to EUS staging. They concluded that surgical staging improved the accuracy of lymph node staging by 16%.¹⁰⁰

Krasna led the CALGB 9380 prospective trial looking at the feasibility of surgical staging with laparoscopy and right VATS and found that the approach was feasible and that the number of positive lymph nodes doubled when compared to those detected by less invasive staging modalities.⁹⁷ An unanswered question, as it was not an endpoint of the study, is what is the cost-effectiveness of surgical staging? Since these earlier studies were carried out, PET-CT and EUS techniques have improved staging enough to conclude that surgical staging is not considered the standard of care mostly because the added costs and patient morbidity do not outweigh the small potential benefit. Given the controversy of managing cT2N0 patients, however, perhaps there may be a role for surgical staging of this subset of patients as minimally invasive surgical staging is superior to EUS staging alone for assessing N status.¹⁰⁰

BRAIN IMAGING

Brain metastases from esophageal cancer are rare. Brain metastases were detected at initial diagnosis of esophagus cancer in 1.7% to 5% of patients in large series of patients with adenocarcinoma or SCC.¹⁰²⁻¹⁰⁴ Brain metastases in a recent series of 27 patients with esophageal cancer (82% adenocarcinoma) was associated with a median survival of 3.8 months.¹⁰⁴ After potentially curative esophagectomy, intracranial metastases occur in an estimated 2% of patients in multiple series.¹⁰⁵ Esophageal metastases are typically to liver, lung, bone, and, in rare cases, adrenal gland and kidney. In a series of 27 (1.7% of all esophagus cancer patients) patients with esophageal brain metastases over an 8-year period, only one presented with the brain metastasis as the index sign of his esophagus cancer.¹⁰⁵ Of

916 patients presenting for whole brain irradiation for brain metastases, only 6% originated from the gastrointestinal malignancies and none from the esophagus.¹⁰⁶ In a high-volume esophageal cancer center, however, 28% of patients presenting for stereotactic radiosurgery for gastrointestinal tract brain metastases had esophageal primaries.¹⁰⁷ Most reports of patients developing brain metastases identify stage IV disease after potentially curative resection.¹⁰⁸⁻¹¹⁰ In one Japanese study of 803 patients treated for brain metastases, 2% originated from primary esophageal cancer (52% SCC).¹⁰⁹ The authors recommended whole brain irradiation to improve median survival from 18 to 66 months in patients who underwent metastasectomy or stereotactic radiosurgery.¹⁰⁹ Other Japanese groups have found the brain as sole site of recurrent disease in 2% of patients and a median survival of 17 months post craniotomy and resection.^{108,111}

Currently the indications for a brain scan (either CT or MRI) for a patient initially presenting with esophagus cancer are similar as for other patients with solid tumors, which would be new-onset headaches or neurologic complaints, including ataxia, paresthesias, or weakness. As routine CT scanning of the brain was not cost effective at the University of Michigan, the authors did note that risk factors for brain metastases included large, locally and regionally advanced primary cancers.¹⁰²

What about restage scanning after neoadjuvant treatment and before potential resection? There is evidence from the Cleveland Clinic that there is a higher occurrence of brain metastases in esophageal cancer patients treated with neoadjuvant or adjuvant chemotherapy and that the adjuvant treatment itself may facilitate development of brain metastases.¹⁰⁵ The significance of this concept is that we may not yet know the role of routine brain MRI or CT in patients treated with neoadjuvant therapy prior to esophagectomy. Although the incidence is low and guidelines of neuropathy or headache should dictate evaluation for brain metastases, in standard practice most patients get a brain MRI before a potentially morbid esophagectomy.

MOLECULAR STAGING: PROGNOSTIC BIOMARKERS

Clinical staging techniques have advanced with the addition of EMR for Tis and T1a tumors; however, solutions are still needed to address controversial areas such as the cT2N0 tumors. Because of weaknesses of EUS with inaccurate T staging and inadequate N sensitivity, initial treatment for these patients is either an esophagectomy or neoadjuvant therapy, most commonly as chemoradiation. Certain tumor characteristics in a cT2N0 patient such as poor differentiation or lymphovascular invasion may sway an esophagectomy-inclined tumor board to refer a patient for induction therapy.

The literature on molecular profiling of esophageal cancers is slowly growing. Some early prognostic predictors of survival include distinct microRNA (miRNA) profiles¹¹² and gene expression variants of cyclin D1 gene expression.¹¹³ Given the 30% to 40% overall response rate of esophageal cancers to induction chemotherapy,

molecular analysis of esophageal tumors could allow for targeted, smart induction therapy. Pretreatment gene expression profiles to predict response to chemoradiation therapy has been shown to be significant in several studies in both SCC and EAC,¹¹⁴⁻¹¹⁶ and there's increasing evidence that gene expression profiling of tumors may help predict an individual patient's response to chemotherapy.¹¹⁷ Microarray analysis of gene expression profiles also should help identify targeted therapy tailored to an individual patient's tumor.^{118,119} Although pathologic response to chemoradiation has been associated with molecular subtypes of endoscopic biopsies in preliminary studies,¹¹⁵ the significant genes and proteins have not been validated through prospective studies.

Molecular studies to date on gene expression profiling as a prognostic marker and not a predictive marker of treatment response include integrated array comparative genomic hybridization (a-CGH) and gene expression to find a prognostic signature based on aberrant regions of interest and worse patient survival.¹²⁰ Chromosomal aberrations correlated with patient survival in a pathology study by Pasello and coworkers,¹²¹ in which multiplex ligation-dependent probe amplification (MLPA) technique was used on 33 resected EACs. With this technique, which is robustly similar to a-CGH, the total number of genomic aberrations correlated with significantly worse survival. Applying these techniques to primary tumors may allow stratification of early-stage patients to induction therapy.

Another approach for early-stage, cT1/2N0 tumors is to use gene signature profiling to classify the tumors as being more likely to have nodal involvement. Although such results have not been reported, there are several gene and protein signature studies that support incorporating molecular staging into the current TNM stage and again supporting stratification to induction or post-resection therapy. A four-gene signature was reported by the Esophageal Cancer Clinical And Molecular Stratification (OCCAMS) study group, to correlate with survival in node-positive patients and was an independent prognostic factor over TNM staging alone.¹²² More recently the same investigators collaborated with esophageal centers and found that a three-gene immunohistochemical panel of EGFR, TRIM44, and SIRT2 portended a worse survival.¹²³ Expression of miRNA, the ubiquitous regulators of gene translation, have also been shown in several studies to associate with survival in both adenocarcinoma and SCC.¹²⁴⁻¹²⁶

We can begin however to envision a future staging system of genomic profiling esophageal cancers where the easily accessible endoscopic biopsies of esophageal cancer would allow for molecular staging. Integrated genetic profiling of primary tumors includes gene and protein expression and, with validation trials, molecular staging could be complementary to current staging modalities with their inherent weaknesses. Therapeutic stratification of patients would include endoscopic mucosal resectional therapy, targeted induction therapy, traditional neoadjuvant therapy, minimally invasive esophagectomy, en bloc esophagectomy, palliative therapy, definitive chemoradiation therapy or perhaps no therapy.

FIGURE 37-1 ■ An algorithm for staging a thoracic esophageal cancer patient. Metastatic disease must always be confirmed by pathologic evaluation of the tissue in question. *PET-CT*, Positron emission tomography-computed tomography.

SUMMARY

The incidence of EAC is on the rise in the United States, and treatment and staging modalities are evolving to translate into a much needed improvement in survival rates. Appropriate staging of the patient with a newly diagnosed esophageal cancer will translate into appropriate triage of patients for esophagectomy, thus contributing to best outcomes in survival rates after resection. Complete clinical staging with EUS, PET-CT, and, in early cancer cases, EMR, and discussion of the results at a multidisciplinary team meeting improve patient selection for induction therapy and esophagectomy.³⁹ The staging algorithm outlined in Figure 37-1 applies to most patients with thoracic EAC and SCC under the recently revised TNM staging system.

Molecular staging of tumors is still not ready for inclusion in the staging system; however, we are getting closer. Our energy should be directed at improving esophageal biomarkers for prognostic and therapeutic management. We look forward to advances in this area so we may optimize clinical staging and targeted treatment to improve patient survival.

SUMMARY

The prevalence of esophageal adenocarcinoma has risen dramatically over the past three decades. Esophageal cancer is the eighth most common cancer worldwide, and more than 480,000 new cases were diagnosed in 2008. The documented increase is approximately six- to seven-fold,¹ with adenocarcinoma now contributing to approximately 80% of the esophageal cancer surgical workload in many surgical units. This increase is unprecedented

and has occurred at a faster rate than for any other cancer.²

Treatment of this disease continues to represent a formidable challenge. According to American Cancer Society's *Cancer Facts & Figures, 2013*, the overall 5-year survival rate for all patients is 19%. Despite the common practice of incorporating chemotherapy or chemoradiotherapy into the treatment paradigm, surgical resection

remains the cornerstone of most treatment protocols for early-stage and locally advanced disease.³ Today patients treated with an esophagectomy have a 5-year survival rate close to 35%.⁴

HISTORY OF ESOPHAGEAL RESECTION

The first esophageal resection was performed more than 125 years ago, yet it remains one of the most formidable operations, carrying the highest morbidity rate of any commonly performed resection. The perioperative mortality rate has decreased from 40% to less than 3% in selected academic centers, largely because of advances in surgical and anesthetic technique, intensive care, and management of complications. The rate of morbidity for this surgery has not decreased as dramatically as has the rate for mortality. With average mortality rates at 10% and complication rates exceeding 50%, careful selection of patients, thoughtful surgical planning, meticulous technique, and timely management of complications are essential to ensure good outcome for the patient.

In general, the principle objective for the surgeon is to balance oncologic principles of clear surgical margins and adequacy of lymphadenectomy with the risks associated with the planned operative approach on a case-by-case basis. Patient and tumor-related characteristics should play a pivotal role in the surgical decision making rather than individual or institutional practice patterns.

The esophageal surgeon must be familiar with the anatomy of the neck, chest, and abdomen and be skilled in surgery of the entire alimentary tract to provide complete care of the patient requiring esophageal resection. Only with this knowledge can the surgeon fit the operation to the patient, not the patient to the operation. These issues are detailed in this chapter.

Ivor Lewis, writing in 1946, is credited with popularizing transthoracic resection of the esophagus. He initially performed the operation in two stages, first mobilizing the stomach through a laparotomy and second, several days later, resecting the esophagus and performing an intrathoracic anastomosis through a right thoracotomy. Lewis showed a sophisticated understanding of the challenges involved in esophageal surgery when he stated that “the oesophagus is a difficult surgical field for three reasons: its inaccessibility; its lack of a serous coat, and its enclosure in structures where infection is especially dangerous and rapid.”⁵ The Ivor Lewis and transhiatal approaches are the most commonly used techniques of esophageal resection today. In 1962, McKeown described a three-stage esophagectomy, with the addition of a cervical incision and anastomosis to allow better margins for proximal tumors.⁶ It is now called the three-hole or tri-incisional esophagectomy.

Open esophagectomy has up to 60% reported morbidity.^{7,8} For this reason, several approaches have been supplemented with thoracoscopic or laparoscopic modifications. Since Cuschieri and colleagues first introduced the concept of a minimally invasive approach to esophagectomy in 1992,⁹ there have been numerous descriptions in the literature.¹⁰⁻¹⁵

TECHNIQUES OF ESOPHAGEAL RESECTION

Modified McKeown or Tri-incisional Technique

Indications

The tri-incisional esophagectomy (modified McKeown) is a versatile technique that can be used for tumors at any level and for various benign and malignant conditions. It combines the advantages of the Ivor Lewis approach with those of a transhiatal technique. These include complete lymph node dissection in the chest, direct visualization of the intrathoracic dissection, avoidance of an intrathoracic anastomosis, maximal margins, and diminution of chances for postoperative gastroesophageal reflux disease. It is especially useful for tumors of the mid and upper esophagus and for tumors arising in a long Barrett segment where almost total excision of the esophagus is required.

Contraindications

Fusion of the right pleural space or inability to support ventilation with the left lung would make an approach through a right thoracotomy difficult. Relative contraindications include small gastric conduits secondary to tumor or limited vascular supply. Patients with tumor extending onto the stomach require more gastric resection than do those with tumor isolated to the esophagus. These patients are most suited for an Ivor Lewis or a jejunal reconstruction if there is not enough stomach.

Preparation

A detailed history and physical examination are necessary to evaluate for coexistent comorbid disease. Computed tomography and positron emission tomography of the chest and abdomen should be performed to evaluate for metastatic disease, anatomic abnormalities, and location of the tumor adjacent to vital structures. Pulmonary function tests should be obtained. Poor forced expiratory volume in 1 second (FEV₁) is not a contraindication to a muscle-sparing limited thoracotomy, although increased risk of pulmonary complications may be expected. Computed tomography and positron emission tomography of the head are useful in ruling out metastatic disease. Preoperative bowel preparation is generally done in the rare and unfortunate case in which there needs to be a change in conduit.

Technique

Esophagogastroduodenoscopy is performed to identify the location of the tumor and to rule out disease of the stomach or duodenum. Retroflexion of the esophagogastroduodenoscopy is important for proper evaluation of the gastroesophageal junction. The carina is at the level of 25 cm from the incisor on esophagogastroduodenoscopy. Tumors in this area should be carefully evaluated by bronchoscopy for tumor invasion of the trachea. A double-lumen tube is placed, and the patient is positioned

in a left lateral decubitus position. A right posterolateral thoracotomy incision is made wide enough to insert the surgeon's hand (approximately 10 cm). A portion of the latissimus is divided; the serratus is spared (Fig. 38-1). Division of the intercostal muscle from the vertebral bodies posteriorly to the mammary vessels anteriorly usually provides enough working space without division of a rib. The chest is entered through the fifth or sixth interspace, depending on the location of the tumor.

The lung is retracted anteriorly, and the inferior pulmonary ligament is divided with use of cautery. In a region away from the tumor and away from any scarring, the pleura overlying the esophagus is incised anteriorly and posteriorly and the esophagus is surrounded with a Penrose drain. With traction on the Penrose drain, the esophagus is retracted both anteriorly and posteriorly and is dissected by electrocautery, including all adjacent lymph node tissue. Arterial branches supplying the esophagus from the aorta are clipped before being divided. Any cautery performed in the region of the

carina must be at low settings to avoid thermal injury to the trachea. The azygos vein is typically divided. At the level of the azygos vein, the vagus nerves are identified on the esophagus and divided between clips. Division of the vagal nerve is important because an intact vagus nerve can lead to a traction injury of the recurrent laryngeal nerve. Further cranial dissection proceeds with the vagus nerves away from the esophagus to avoid recurrent nerve injury. Blunt dissection is useful high in the right chest (Fig. 38-2). Most dissection should be in the posterior plane to avoid injury to the recurrent laryngeal nerve, which is in the groove between the esophagus and trachea. A knotted Penrose drain is placed around the cervical esophagus and pushed into the posterior neck for retrieval during the cervical portion of the case (Fig. 38-3). This Penrose drain, positioned inside the vagus nerves relative to the esophagus, permits isolation of the cervical esophagus without traction on the recurrent nerve. A sponge is packed high in the chest to assist in hemostasis and is removed before closure. The lower portion of the esophagus is encircled with a second Penrose drain and the remaining distal esophagus is dissected, including in the specimen all tissue lateral to the pericardium and medial to the aorta and spine.

If the tumor is near the gastroesophageal junction, a 2-cm rim of diaphragm is resected with the esophagus (Fig. 38-4). The Penrose drain is knotted and left in the abdomen for retrieval during the abdominal portion of the operation. Mass ligation of the thoracic duct at the level of the hiatus is performed by encircling all tissue between the aorta and spine with a 0 silk suture. The chest is inspected for hemostasis, the sponge previously

FIGURE 38-4 ■ A rim of diaphragm is incorporated into the specimen for all gastroesophageal junction tumors. A knotted Penrose drain is placed into the abdomen to aid dissection of the esophagus at the gastroesophageal junction during the abdominal phase of the operation. (From Sugarbaker D, DeCamp M, Liptay M: Surgical procedures to resect and replace the esophagus. In Zinner M, Schwartz S, Ellis H, et al, editors: *Maingot's abdominal operations*, Stamford, CT, 1997, Appleton & Lange, pp 885–910.)

FIGURE 38-5 ■ The phrenoesophageal ligament is divided fully after retrieval of the Penrose drain. (From Swanson S, Grondin S, Sugarbaker D: Total esophagectomy: the Brigham and Women's Hospital approach. *Oper Tech Thorac Cardiovasc Surg* 4:197–209, 1999.)

placed is removed, and a 28 Fr straight chest tube is inserted through a separate stab incision and directed to the apex of the chest. The ribs are approximated with interrupted #2 Vicryl sutures. The latissimus is closed with running 0 Vicryl suture. The subdermal fascia is closed with a running 2-0 Vicryl suture. The skin is closed with staples or suture. The patient is repositioned in the supine position and is reintubated with a single-lumen tube. A transverse roll is placed under the scapula, and the head is turned 45 degrees to the right. An upper midline laparotomy is performed from the umbilicus to the junction of the costal margin and the left side of the xiphoid; the xiphoid is occasionally resected for better visualization. The abdomen is explored for metastatic disease, which includes inspection of the liver, omentum, and peritoneal surfaces. The left lobe of the liver is mobilized by dividing the triangular ligament. Close to the triangular ligament are large diaphragmatic veins that should be avoided during this dissection. The Penrose drain surrounding the gastroesophageal junction is grasped, and the remaining phrenoesophageal ligament is divided (Fig. 38-5). The gastroepiploic pulse is palpated. At a point 2 cm away from the gastroepiploic artery on the greater curvature of the stomach, the lesser sac is entered. Dissection along the greater curvature of the stomach toward the spleen proceeds with division of vascular branches by use of double clips, silk ties, or the harmonic scalpel. Short gastric vessels are taken in identical fashion. Displacement of the spleen anteriorly by placement of lap pads behind the spleen may aid in

dissection of the short gastric vessels. Once the short gastric arteries are divided, additional dissection toward the pylorus is performed. The gastroduodenal artery travels behind the pylorus before branching into the right gastric epiploic and superior pancreaticoduodenal arteries. The duodenum is mobilized from its retroperitoneum connections by a Kocher maneuver. The duodenum is adequately mobilized when the pylorus can reach the esophageal hiatus.

The stomach is then lifted anteriorly, and any adhesions between the stomach and pancreas are divided with electrocautery. The left gastric artery is identified and skeletonized, sweeping lymph node tissue onto the specimen. With a 30-mm vascular stapler, the base of the left gastric artery is clamped. A continued strong pulse in the gastroepiploic artery is confirmed, and the left gastric artery is divided (Fig. 38-6). The gastrohepatic ligament is divided by a combination of cautery and the stapler. Either a pyloromyotomy or a pyloroplasty may be performed. If a pyloroplasty is performed, it should be a single layer with interrupted 3-0 silk sutures, carefully incorporating mucosa and muscular wall.

Attention is then turned to the neck, and a 6-cm incision is made from the sternal notch along the anterior border of the sternocleidomastoid muscle. The platysma is divided, and dissection proceeds between the carotid sheath laterally and the strap muscles medially. The omohyoid muscle may be divided. The knot of the Penrose drain should be palpable on the spine. The Penrose drain is grasped, and the esophagus is gently mobilized. The nasogastric tube is partially withdrawn, and the cervical esophagus is divided with a 75-mm linear stapler (Fig. 38-7). A #2 silk suture ligature is fastened to the distal end of the divided esophagus, and the specimen is drawn

into the abdomen with the attached silk suture. The cervical end of the silk suture is fastened to a clamp.

A gastric tube is fashioned by resecting the gastroesophageal junction and the lesser curve of the stomach with a series of 75-mm-thick tissue staples (Fig. 38-8). A narrow gastric tube aids in gastric emptying. A diameter

FIGURE 38-7 ■ Retrieval of the Penrose drain placed around the esophagus inside the recurrent nerves during chest dissection. This aids in the prevention of recurrent nerve injury. The esophagus is divided after removal of the nasogastric tube. (From Sugarbaker D, DeCamp M, Liptay M: Surgical procedures to resect and replace the esophagus. In Zinner M, Schwartz S, Ellis H, et al, editors: *Maingot's abdominal operations*, Stamford, CT, 1997, Appleton & Lange, pp 885-910.)

FIGURE 38-6 ■ After complete mobilization of the greater curvature of the stomach and division of the gastrohepatic ligament, the left gastric vessels are identified. An endoscopic vascular stapler is used to divide these vessels, with care taken not to impinge on the celiac axis. (From Sugarbaker D, DeCamp M, Liptay M: Surgical procedures to resect and replace the esophagus. In Zinner M, Schwartz S, Ellis H, et al, editors: *Maingot's abdominal operations*, Stamford, CT, 1997, Appleton & Lange, pp 885-910.)

FIGURE 38-8 ■ The gastric tube is created after complete dissection of the stomach and after the cervical esophagus is divided and brought into the abdomen. The gastric tube should be kept at least 5 cm in diameter. This also allows longer margins for gastroesophageal junction tumors. A pyloroplasty has been performed. (From Swanson S, Grondin S, Sugarbaker D: Total esophagectomy: the Brigham and Women's Hospital approach. *Oper Tech Thorac Cardiovasc Surg* 4:197-209, 1999.)

of less than 6 cm, however, can compromise venous and arterial blood supply. The line of division ends at a point on the lesser curve near the crow's-feet of veins. At this point along the lesser curve, the right gastric artery and associated tissue can be divided to maximize conduit length.

With the specimen removed, a final check for hemostasis is made in the bed of the stomach and spleen. Before the conduit is pulled into the neck, the esophageal hiatus should be dilated to four fingers. The gastric conduit may be pulled to the neck in relatively atraumatic fashion by the use of an endoscopic camera bag attached to a Foley catheter. The heavy silk tie that traverses the mediastinum from the neck is tied to the valved end of a 30-cm three-way Foley urinary catheter.⁶ The endoscopic bag is secured to the Foley balloon. The conduit is placed in the bag, and the valved end is drawn into the neck (Fig. 38-9). The assistant must guide the conduit through the hiatus and up the lower mediastinum, ensuring that there is no torsion. The bag is cut away from the conduit in the neck, and the conduit is grasped with a Babcock instrument. The pylorus should sit at the hiatus. A side-to-side, functional end-to-end stapled anastomosis may be performed. The anastomosis is created with a 75-mm linear stapler followed by a 30-mm endoscopic

stapler. Alternatively, the neck anastomosis can be hand sewn with interrupted circumferential full-thickness 3-0 silk sutures (Fig. 38-10). The nasogastric tube is advanced across the anastomosis and positioned just proximal to the pylorus before closure of the remaining anastomotic defect (Fig. 38-11). A drain is placed along the spine posterior to the anastomosis, and the platysma is run closed with 2-0 Vicryl sutures. The skin is closed with staples. A feeding tube is inserted in the jejunum at a point 40 cm distal to the ligament of Treitz. The abdominal fascia is closed with a running #2 monofilament suture, and the skin is closed with staples.

Ivor Lewis Esophagectomy

Indications

The indications are similar to those for a tri-incisional approach.

Contraindications

Tumors located in the upper third of the thoracic esophagus, above the carina, are better approached with resection of the cervical esophagus and anastomosis in the neck to ensure adequate margins. Long-segment Barrett esophagus with extension into the cervical esophagus is also a contraindication to an anastomosis in the right chest. A fused pleural space or severely compromised lung function should lead to reconsideration of a thoracotomy.

FIGURE 38-9 ■ An endoscopic camera bag is used as an atraumatic means of drawing the conduit into the neck for anastomosis. Suction is applied to the Foley catheter as it is pulled into the neck. (From Sugarbaker D, DeCamp M, Liptay M: Surgical procedures to resect and replace the esophagus. In Zinner M, Schwartz S, Ellis H, et al, editors: *Maingot's abdominal operations*, Stamford, CT, 1997, Appleton & Lange, pp 885-910.)

FIGURE 38-10 ■ The cervical anastomosis may be hand sewn with interrupted silk sutures over a nasogastric tube. (From Swanson S, Grondin S, Sugarbaker D: Total esophagectomy: the Brigham and Women's Hospital approach. *Oper Tech Thorac Cardiovasc Surg* 4:197-209, 1999.)

FIGURE 38-11 ■ **A**, A corner of the proximal esophageal staple line is trimmed, and an enterotomy is made in the proximal gastric conduit away from the staple line. **B**, A gastrointestinal anastomosis stapler is used to create the back wall of the cervical anastomosis. Additional length may be obtained with an additional fire of an endoscopic 30-mm stapler. **C**, The anterior wall of the anastomosis is closed with a thoracoabdominal stapler. In this illustration, a gastric drainage tube exits through the neck. These tubes can be used in place of a nasogastric tube and are more comfortable for the patient. (From Swanson S, Grondin S, Sugarbaker D: Total esophagectomy: the Brigham and Women's Hospital approach. *Oper Tech Thorac Cardiovasc Surg* 4:197-209, 1999.)

Technique

The patient is positioned supine. Preoperative bronchoscopy and esophagogastroduodenoscopy are performed. An upper midline incision is made extending from the umbilicus to the xiphoid. The abdominal portion of the

operation is identical to that described for a tri-incisional esophagectomy, with complete mobilization of the stomach, kocherization of the duodenum, pyloroplasty, construction of the gastric tube, and placement of a J tube. The conduit is advanced into the chest as far as possible before the abdomen is closed. After placement

of a double-lumen endotracheal tube, the patient is repositioned in the left lateral decubitus position, and a standard right posterolateral thoracotomy is performed. Entry into the chest is through the fourth or fifth interspace. The azygos vein is divided and the intrathoracic esophagus is dissected, including all adjacent areolar and lymphatic tissue. A margin of at least 5 cm and ideally 10 cm is desirable, and thus the anastomosis is usually performed high in the right chest. The esophagus is dissected free to a point only several centimeters above the proposed line of transection to preserve blood supply to the anastomosis. The esophagus is divided and the stomach is pulled up, and the gastric conduit is fashioned with a gastrointestinal anastomosis (GIA) stapler. Various techniques may be used to perform the anastomosis, including single-layer hand sewn, double-layer hand sewn, end-to-end stapled, and side-to-side functional end-to-end stapled.

With all techniques, wrapping of the anastomosis with omentum and passage of the nasogastric tube before completion of the final portion of the anastomosis are advised. A stapled anastomosis may be performed in a side-to-side, functional end-to-end manner with creation of the anastomosis by a GIA 75-mm or sequential 30-mm endoscopic stapler and closure of the defect with a thoracoabdominal (TA) 30-mm or 60-mm stapler. A similar technique involves lining up the gastric conduit and esophagus in a linear fashion and stapling the back wall of the anastomosis with a linear stapler or endostapler and sewing the front wall by either a one- or a two-layer technique. This type of approach is used in the neck as described by Orringer. The anastomosis can also be performed with an end-to-end anastomosis (EEA) stapler, although anastomoses created with EEA staplers smaller than 33 mm carry a significant risk of stricture.¹⁶ With the EEA stapler, passage of the nasogastric tube is, of course, performed after completion of the anastomosis.

If a hand-sewn anastomosis is to be performed, the proximal esophagus is divided with a knife after clamping the esophagus proximally with a noncrushing bowel clamp. A single-layer anastomosis is performed with interrupted 3-0 silk stitches with full-thickness bites of the mucosa and muscularis and careful approximation of tissues. Knots on the posterior row may be tied inside the

lumen (Fig. 38-12).¹⁷ A double-layer anastomosis was described by Churchill and Sweet in 1942.^{18,19} At a point at least 2 cm beyond the staple line, a 2-cm-diameter area of gastric serosa is scored. Underlying vessels are ligated with interrupted silk sutures. The posterior layer of the anastomosis is created with interrupted 3-0 silk stitches. An inner, full-thickness layer is performed with a fine 4-0 absorbable suture, either catgut or Monocryl, by a running Connell stitch to invert the mucosa. Before completion of the inner layer, the nasogastric tube is passed to the hiatus. An anterior outer layer is then performed with interrupted 3-0 silk. Omentum is used to wrap the anastomosis. The distal portion of the stomach is reduced into the abdomen to avoid excess redundancy of the stomach in the chest, which might impair conduit emptying. Stitches are placed anchoring the conduit to the diaphragmatic hiatus. Some surgeons use additional stitches anchoring the intrathoracic conduit to the pleura, although the effectiveness of these stitches is debated.

Transhiatal Esophagectomy

Indications

Some physicians believe that transhiatal esophagectomy is ideally suited for benign esophageal disease and possibly Barrett esophagus with high-grade dysplasia, for which complete lymphadenectomy may not be necessary. Other factors, such as poor pulmonary function (FEV_1 <800 mL or <35% predicted) and pleural symphysis, would favor a technique that avoids a thoracotomy.

Contraindications

Bulky tumors of the midthoracic esophagus are difficult to visualize from the transhiatal approach, and injury to adjacent structures may occur. Scarring after neoadjuvant treatment of esophageal tumors may also make the transhiatal approach difficult. The need to perform a complete lymphadenectomy is a contraindication to this approach.

The presence of severe coronary or valvular disease makes the episodic drops in blood pressure associated with blunt dissection behind the heart especially

FIGURE 38-12 ■ The Ivor Lewis anastomosis is performed at the level of the azygos vein, in two layers, after creation of a circular enterotomy in the proximal conduit. The edges of the conduit are shown here tacked to the pleura, although it is debatable whether this effectively reduces tension on the anastomosis. (Adapted from Sugarbaker D, DeCamp M, Liptay M: Surgical procedures to resect and replace the esophagus. In Zinner M, Schwartz S, Ellis H, et al, editors: *Maingot's abdominal operations*, Stamford, CT, 1997, Appleton & Lange, pp 885–910.)

treacherous. A transthoracic approach may be preferable in these cases.

Preparation

The preparation is identical to preparation for a trincisional esophagectomy.

Technique

Bronchoscopy and esophagogastroduodenoscopy are performed as previously described. The abdominal portion of the procedure is performed as described in the previous section. An upper hand retractor aids in raising the xiphoid and sternum for visualization of the mediastinum. The esophagophrenic attachments are divided with cautery, the gastroesophageal junction is separated from the crura, and the distal esophagus is encircled with a Penrose drain. The hiatus is dilated to allow entry of the surgeon's hand. Various hand-held malleable retractors may be used in dissection of the mediastinum through the hiatus. With the use of the Penrose drain to retract the lower esophagus, the lower esophagus is dissected through the hiatus. Arterial branches supplying the lower esophagus from the aorta are clipped under direct vision. With the fingertips against the esophagus, the esophagus is dissected off the vertebral plane bluntly into the upper chest. The palmar aspect of the fingertips is kept directly against the esophagus. Arteries supplying the esophagus branch approximately 1 cm away from the esophagus, and dissection close to the esophagus disrupts only the smaller arterial branches directly entering the esophagus. Close dissection of the esophagus also avoids injury to adjacent structures. A cervical incision is made along the lower border of the left sternocleidomastoid muscle. Dissection proceeds as described in the previous section with the exception that the esophagus must be identified and encircled from the neck. An approach from the left side of the neck aids in avoiding injury to the right recurrent laryngeal nerve, which is farther from the esophagus than the left recurrent nerve at this level. Dissection is kept immediately on the esophagus to avoid recurrent nerve injury. Metal retractors should not be placed near the tracheoesophageal groove. A Penrose drain is placed around the cervical esophagus.

Dissection caudally is performed with two fingers against the esophagus in the posterior plane. Depending on the length of the surgeon's fingers and the width of the abdominal surgeon's hand, it should be possible for the two hands to contact directly. A thin plane of tissue remains, which must be torn for the two hands to touch. Alternatively, a sponge stick can be advanced posteriorly from the neck to touch the dissecting hand from the abdomen (Fig. 38-13). Dissection then proceeds in a similar fashion on the anterior surface of the esophagus. Extreme care must be taken in the region of the trachea and especially the carina to avoid injury to the membranous trachea. (At this point in the operation, any difficulty in dissecting the esophagus from the trachea or any concern of adhesion to, or invasion of, the trachea should result in repositioning of the patient in the left lateral decubitus position, and a right thoracotomy should be

FIGURE 38-13 ■ Posterior dissection is performed with the fingertips adjacent to the esophagus. Dissection from the cranial aspect may be performed with a sponge stick if the surgeon's upper hand cannot reach the lower hand. (Adapted from Orringer MB, Sloan H: Esophagectomy without thoracotomy. *J Thorac Cardiovasc Surg* 76:643–654, 1978.)

performed for direct visualization and dissection.) The fingers from above and below should meet in the region of the carina (Fig. 38-14).

As much dissection as possible should be performed under direct vision from the neck and from the abdomen. Portions of the lateral dissection near the lower aspect of the trachea often cannot be visualized, and lateral dissection must be performed bluntly. The surgeon's right hand is advanced from the abdomen high up in the chest to the point where circumferential dissection has been completed from the neck. The first and second fingers surround the esophagus, and with a raking motion, the lateral attachments are avulsed as the hand is drawn back into the abdomen. Care must be taken near the region of the azygos vein (Fig. 38-15). After complete mobilization of the esophagus, it is divided in the neck, and the specimen is brought out into the abdomen. The mediastinum is packed for hemostasis. Before the gastric tube is drawn up into the neck, the mediastinal packing is removed and both pleural spaces are inspected for integrity. Entry into the pleural space is managed by chest tube placement before removal of the drapes.

FIGURE 38-14 ■ **A**, Blunt dissection of the esophagus off of the trachea is performed with the fingertips immediately against the esophagus. **B**, The fingertips are united. The fingertips from above should be able to reach near the carina, as they do during cervical mediastinoscopy. (Adapted from Orringer MB: Transhiatal esophagectomy without thoracotomy. In Cohn LH, editor: *Modern techniques in surgery*, New York, 1983, Futura Publishing.)

Trials Comparing Transhiatal with Transthoracic Resection

Numerous nonrandomized, retrospective trials have been performed in an attempt to define differences in either perioperative complication rate or long-term survival between the transhiatal and transthoracic approaches (Table 38-1).²⁰⁻²² Most of these were limited by small study size and selection bias. A large meta-analysis review was performed by Rindani and coworkers²³ in 1999. Forty-four trials published in the English literature between 1986 and 1996 consisting of 5483 patients undergoing either Ivor Lewis or transhiatal esophagectomy were reviewed. The overall incidence of pneumonia was 25%, and it was not appreciably different between the two techniques. The incidence of bleeding and cardiac complications was also not different. The most significant differences were seen in the anastomotic leak rate (16% transhiatal vs. 10% Ivor Lewis), stricture (28% transhiatal vs. 16% Ivor Lewis), and recurrent nerve injury (11% transhiatal vs. 5% Ivor Lewis). Perioperative

TABLE 38-1 Comparison of Transthoracic and Transhiatal Approaches to Esophagectomy: Perioperative Complications

Complication	Transthoracic	Transhiatal
Blood loss (mL)	1001	728
Operative time (hours)	5.6	4.0
Cardiac complications (%)	6.6	19.5
Pulmonary complications (%)	18.7	12.7
Anastomotic leak (%)	7.2	13.6
Vocal cord paralysis (%)	3.5	9.5
Chyle leak (%)	2.4	1.4
In-hospital mortality (%)	9.2	5.7

FIGURE 38-15 ■ After dissection of the anterior and posterior planes, the lateral stalks can be torn between the first and second fingers in a “raking” motion. (Adapted from Orringer MB: Transhiatal esophagectomy without thoracotomy. In Cohn LH, editor: *Modern techniques in surgery*, New York, 1983, Futura Publishing.)

mortality was higher in the Ivor Lewis population (9.5%) than in the transhiatal population (6.3%). Overall long-term (5-year) survival was similar in the two groups, 25%. Hulscher and colleagues²⁴ also performed a meta-analysis of trials between 1990 and 1999 published in English language journals. Fifty publications were identified, some randomized, some comparing transthoracic with transhiatal approaches, and some evaluating only one technique. Overall, cardiac complications (20% vs. 7%), anastomotic leakage (14% vs. 7%), and vocal cord paralysis (10% vs. 4%) were higher in the transhiatal versus the transthoracic groups. Pulmonary complications (19% vs. 13%), in-hospital mortality (9% vs. 6%), and operative time (5.6 vs. 4.0 hours) were higher in the transthoracic versus the transhiatal group. Overall 5-year survival was similar among all the studies and patients evaluated (23% for transthoracic resections and 21.7% for transhiatal resections). These reviews are of historical and factual interest only, and little can be concluded about the relative merits of each technique in matched populations.

Orringer and colleagues²⁵ reviewed their 30-year experience with transhiatal esophagectomies in 2007 patients. The patients were divided into two groups: group I, those operated on between 1976 and 1998; and group II, those operated on from 1998 to 2006. Postoperative mediastinal bleeding requiring reoperation occurred in less than 1%. The incidence of recurrent laryngeal nerve injury was significantly lower in group II (2%) compared with group I (7%; $P < 0.0001$). They believed that this decrease in injury was secondary to an increase in operative volume. Chylothorax was seen in 1%. The incidence of respiratory complications that required a hospital stay beyond 10 days was 2%. They also reported that the routine use of side-to-side stapled cervical esophagogastric anastomosis after 1997 has led

to a notable decrease in leak rate and need for postoperative dilation. The overall hospital mortality was 3%. The hospital mortality fell with increased volume (group I, 4%; group II, 1%). It is clear that the high volume at this center has produced impressive results with regard to transhiatal esophagectomy.

Wolff and associates²⁶ retrospectively reviewed all esophagectomies at the Mayo Clinic between 1994 and 2004. Of the 517 esophagectomies performed, the type of surgery was as follows: transhiatal (68), Ivor Lewis (392), and extended Ivor Lewis (57). The mean lymph nodes retrieved for the Ivor Lewis and extended Ivor Lewis were 18.7 and 17.4, respectively. This was not statistically different. The transhiatal patients had a mean of 8.99 lymph nodes in the specimen. They found that the combined Ivor Lewis group and the transhiatal group were significantly different, showing on average 9.5 lymph nodes in the surgical specimen ($P < 0.001$). The importance of the number of lymph nodes harvested at the time of surgery is discussed in a later section.

Orringer and associates²⁷ reviewed outcomes after transhiatal and transthoracic surgery using the Surveillance, Epidemiology, and End Results (SEER) cancer registry. They identified patients between 1992 and 2002 undergoing esophagectomy. Of the 868 patients studied, 643 had a transthoracic approach and 225 underwent a transhiatal esophagectomy. They concluded that patients undergoing a transhiatal esophagectomy had a lower operative mortality rate than did those undergoing transthoracic operations (6.7% vs. 13.1%; $P = 0.009$). The need for anastomotic dilation was higher in the transhiatal group (43.1%) compared with the transthoracic patients (34.5%; $P = 0.02$). The 5-year survival rate was significantly higher in the transhiatal group; however, this benefit over the transthoracic group was diminished after adjustments were made for patient and hospital or provider characteristics, such as volume performed at the center and involvement of trainees.

Three randomized, prospective trials comparing transhiatal resection with transthoracic resection demonstrated that either technique can be performed safely in skilled hands and no clear differences have been shown between the two techniques, in large part because of an inadequate number of patients enrolled in the trials. Extrapolating from their retrospective meta-analysis, Rindani and colleagues²³ estimated that 2360 patients would have to be randomized for a significant difference to be shown in perioperative mortality, and 6400 patients would be needed for a difference to be shown in long-term survival. Clearly, this is beyond the capacity of any prospective esophagectomy trial.

The first randomized, prospective trial was published in 1993 by Goldmine and coworkers.²⁸ They randomized 67 patients younger than 70 years with squamous cell cancer of the esophagus to Ivor Lewis esophagectomy or transhiatal esophagectomy. Operative time was longer (6 vs. 4 hours) in the transthoracic group. No difference was found in incidence of pneumonia (20%), anastomotic leak, recurrent nerve injury, bleeding, perioperative mortality, or length of hospitalization. At a mean follow-up of 3 years, survival was not statistically different between the two groups. For those patients with nodal disease,

however, none of the transhiatal patients was alive at 18 months, whereas 30% of the transthoracic patients were alive at 18 months.

Wong and colleagues reported a prospective, randomized series of 39 patients with lower third esophageal cancers treated with either an Ivor Lewis resection or a transhiatal resection.²⁹ Patients undergoing neoadjuvant therapy or those with an FEV₁ below 70% were excluded from the study. There were no perioperative (30-day) deaths in either group, although the in-hospital mortality rate was 15% for the transhiatal group and 0% for the transthoracic group (not significantly different). Intraoperative hypotension occurred in 60% of transhiatal patients but in only 5% of transthoracic patients. There was no difference in blood loss, pneumonia, or recurrent nerve injury. Operating time was longer for the transthoracic group. The mean proximal margin was 3 cm longer in the transhiatal group. No significant difference was seen in tumor recurrence or survival. This group recently published their 5-year results from this study.³⁰ After a complete 5-year follow-up, they concluded that overall survival rate was not significantly different between the two groups. However, they reported a trend toward improved survival in the extended transthoracic group over the transhiatal group in the patients with a type I esophageal cancer.

More recently, a randomized study was completed in the Netherlands comparing transhiatal resection with extended transthoracic en bloc resection for distal adenocarcinomas of the esophagus or cardia³¹; 106 patients had a transhiatal resection, and 114 patients had a transthoracic resection. The median follow-up was 4.7 years. The in-hospital mortality rate was 2% to 4% in each group. The incidence of respiratory complications, including atelectasis and pneumonia, was higher in the transthoracic group (57% vs. 27%), as was the incidence of chyle leak (10% vs. 2%). The high incidence of respiratory complications in the transthoracic group (57%) should be questioned, because it is much higher than that quoted in many previous transthoracic resection series.²³ Although statistical significance was not reached, there was a trend toward improved survival at 5 years in the transthoracic group (39% vs. 29%).

Minimally Invasive Esophagectomy

Cuschieri is credited with first applying minimally invasive techniques to an esophagectomy. Since his initial description of subtotal endoscopic esophagectomy using thoracoscopic techniques for mobilization of the esophagus, there have been numerous descriptions with varying degrees of endoscopic involvement. The three most widely performed open procedures for esophageal resection—tri-incisional, Ivor Lewis, and transhiatal esophagectomy—have endoscopic counterparts. These are discussed.

Minimally Invasive Tri-incisional Esophagectomy

Minimally invasive techniques can be used to perform a modified McKeown esophagectomy. All or part of the

procedure may be replaced with thoracoscopic or laparoscopic dissection.

Indications. There are no finite indications for minimally invasive esophagectomy (MIE). There are relative indications advocated by those who specialize in this surgery. These reported benefits of MIE are discussed in a later section.

Contraindications. Fusion of the right pleural space or inability to maintain isolated lung ventilation is a contraindication to the approach. Unlike its open counterpart, video-assisted thoracoscopic esophagectomy requires almost perfect lung isolation to allow adequate room to thoracoscopically maneuver within the thoracic cavity. On occasion, continuous positive airway pressure to the right lung will aid in achieving adequate ventilation and oxygenation with minimal effect on exposure. Relative contraindications with respect to minimally invasive surgery are the same as those in the open sections. As with any endoscopically assisted surgery, the surgeon's comfort is a strong determining factor in use of this technology. Those not trained in minimally invasive surgery should consider performing this highly technical surgery with a surgeon who is facile with this procedure.

Technique

Video-Assisted Thoracoscopic Mobilization of the Thoracic Esophagus. Video-assisted thoracoscopic esophageal mobilization uses four thoracoscopic incisions. After the patient is prepared and draped in the left lateral decubitus position, a 1-cm incision is made in the eighth intercostal space at the posterior axillary line. Ideally, the camera needs to be as posterior as possible for optimal visualization. However, this port will be used for the chest tube, and any position farther posterior will result in an ineffective chest tube because the patient will be lying on it.

With the thoracoscope, the right hemithorax is examined for pleural disease that may prohibit further surgery. Three access incisions are placed next, with two of the ports in line with the tip of the scapula, at the level of the sixth and ninth intercostal spaces. The final access incision will be in the fourth intercostal space in line with the camera. This is used mainly for lung retraction and suctioning of the operative field.

Most surgeons use a port only for the camera. Standard open instruments, such as a ring forceps, are passed through the other incisions without a port. Some surgeons prefer laparoscopic instruments, so they use 5-mm and 10-mm ports to allow easy passage of these surgical tools.

Some surgeons place a stitch in the central tendon of the diaphragm and bring it out through a separate intercostal space to retract the diaphragm. The authors of this chapter place an endoscopic Kittner (Ethicon, Somerville, NJ) alongside the camera to provide gentle caudal retraction on the diaphragm.

Through the posterior ports, the surgeon uses an ultrasonic scalpel, the harmonic scalpel (Ethicon, Somerville, NJ), to divide the inferior pulmonary ligament. The posterior mediastinal pleura is opened, and the lymph nodes are swept off the pericardium toward the

esophagus. This dissection is carried to the azygos vein. The pleura above the azygos vein is opened close to the esophagus. An endovascular stapler is used to ligate the azygos vein. Once this is achieved, the pleura on the posterior aspect of the esophagus is opened at an area away from the tumor and carina. Once circumferentially around the esophagus, a Penrose drain is placed. The Penrose drain is stapled together with an endovascular stapling device. This Penrose drain can be used as a handle to hold the esophagus during dissection. The vagus is divided just above the azygos vein to prevent traction injury to the recurrent laryngeal nerve. The thoracic esophagus is circumferentially dissected for its entire length. The diaphragmatic hiatus is not opened in the chest to allow adequate pneumoperitoneum during the laparoscopic portion. After adequate mobilization, the Penrose drain is placed into the apex of the thoracic cavity to allow retrieval from the neck. A complete thoracic lymphadenectomy is an important aspect of this component of the operation and should be performed routinely. The chest tube is placed, and all thoracic incisions are closed. The patient is turned supine, and the double-lumen endotracheal tube is changed to a single-lumen tube. The patient is prepared and draped for laparoscopic surgery.

Laparoscopic Mobilization of the Gastric Conduit, Pyloroplasty, and Formation of a Jejunostomy Tube. Four 5-mm ports and one 10-mm port are placed as they would be in preparation for a laparoscopic Nissen fundoplication. The liver retractor is used to retract the left lobe of the liver so the underlying esophageal hiatus is visualized. The assistant standing to the patient's left will maintain the camera and provide countertraction for the surgeon. The harmonic scalpel is used to open the gastrocolic ligament. Great care is taken to maintain a 2-cm distance from the gastroepiploic arcade. The short gastric arteries can be divided with the harmonic scalpel. The gastric hepatic ligament is opened to allow access to the right crus of the diaphragm. The lymph nodes along the celiac and left gastric are swept toward the stomach. The left gastric artery is ligated. A gastric tube is created by dividing the stomach starting at the distal lesser curve with use of a 3.5- or 4.8-mm endovascular stapler. The conduit is formed with several firings of the endovascular stapler until this area on the lesser curve is connected with the cardia-fundus of the greater curvature. Once achieved, the proximal gastric tube is attached to the gastric remnant with several Endo Stitch sutures (U.S. Surgical Corp., Norwalk, CT).

A pyloroplasty could be performed with use of the harmonic scalpel to open the pylorus in a longitudinal fashion and placement of interrupted Endo Stitch sutures to close the opening in a transverse manner.³² Recent analysis of literature demonstrated that pyloric drainage procedure was associated with a nonsignificant trend for delayed gastric emptying and biliary reflux, while not affecting the incidence of dumping, and it is not performed routinely by the authors of this chapter.³³

Before a neck dissection is performed, a jejunostomy is created. The ligament of Treitz is identified by elevating the transverse colon. A place on the jejunum, approximately 40 cm from the ligament of Treitz, is attached to

the anterior abdominal wall with the Endo Stitch. A needle catheter kit (Compat Biosystems, Minneapolis, MN) is placed percutaneously into the jejunal loop. The Seldinger technique is used to guide a catheter into the jejunum. The placement is visually confirmed by injecting air into the catheter and watching for jejunal distention.

Finally, a neck incision and dissection are performed as described earlier. The esophagus is pulled out of the neck while an assistant laparoscopically guides the conduit through the hiatus, ensuring proper alignment. The specimen is sent for pathologic examination, and the anastomosis is performed as previously described.

Of interest, Fabian and coworkers³⁴ published a report of 21 patients who had a thoracoscopic mobilization of the esophagus in the prone position. They thought the prone position for thoracoscopic esophageal mobilization to be equivalent to lateral decubitus position with respect to blood loss, number of lymph nodes dissected, and complications. The operative time, however, was significantly reduced in the group of prone patients.

Minimally Invasive Ivor Lewis Esophagectomy

Indications, contraindications, and preparation for this procedure are identical to those for open surgery. After esophagogastroduodenoscopy and bronchoscopy, the patient is prepared and draped in the supine position. The laparoscopic portion of this surgery, including jejunostomy tube formation and pyloroplasty, is almost identical to that for minimally invasive tri-incisional surgery.

After gastric conduit formation and completion of the laparoscopic surgery, a double-lumen endotracheal tube is placed. The patient is prepared and draped in the lateral decubitus position. The thoracoscopic incisions are identical to those described in the minimally invasive tri-incisional section with one exception. The posterior eighth intercostal access incision is 3 to 4 cm to allow placement of a laparoscopic wound protector.³⁵ A combination of the wound protector and lubrication allows easy introduction of the EEA stapler through this port. The esophagus is mobilized to a few centimeters above the azygos vein. The gastroesophageal junction and conduit are then delivered through the hiatus. The proximal esophagus is divided above the azygos vein, and the specimen is brought out the protected port. The anvil of the EEA stapler is secured in the proximal esophagus with an Endo Stitch. The EEA stapler is then maneuvered into the proximal gastric conduit. An end-to-side (esophagus to stomach) circular anastomosis is formed. A linear stapler is used to close the gastric conduit. Chest tubes and standard closure are performed.

Minimally Invasive Transhiatal Esophagectomy

Laparoscopic transhiatal surgery has been described by various centers.³⁶⁻³⁸ The procedure has the same preparation and positioning as a transhiatal esophagectomy. Laparoscopic instruments are used for mediastinal dissection, thus avoiding the blind, blunt dissection done in

open transhiatal surgery. The esophagogastric anastomosis is made in the left neck. Limited visualization of the middle and upper third of the mediastinum and incomplete mediastinal lymphadenectomy are the main criticisms of this surgery. A mediastinoscope placed in the superior mediastinum has been used to help address this concern.³⁹

Results of Minimally Invasive Esophagectomy

Regardless of surgical approach and the use of minimally invasive techniques, esophageal surgery for malignant disease must adhere to certain principles. The procedure must ensure safe and complete resection of the tumor with adequate margins and provide restoration of gastrointestinal continuity. The literature contains numerous descriptions and outcome data of MIE. However, the publications at present are almost entirely composed of case series.

Luketich and associates⁴⁰ at the University of Pittsburgh Medical Center published their results of 222 consecutive minimally invasive esophagectomies performed between 1996 and 2002. The median age was 66.5 years. The indications for surgery were carcinoma (78%) and high-grade dysplasia (21.2%). Of the patients with invasive esophageal cancer, 31 were assigned to stage I, 71 to stage II, and 81 to stage III. Neoadjuvant chemotherapy was given to 78 patients (35.1%) and radiation therapy to 36 patients (16.2%). Fifty-five patients had previous abdominal surgery. A pyloromyotomy was performed in 28 patients and a pyloroplasty in 136 patients. Luketich and coworkers abandoned the pyloroplasty mid series when they made a narrower gastric conduit (4 cm). The leak rate increased, and the pyloroplasty was reinstituted as part of a MIE. A laparoscopic jejunostomy tube was placed in 202 patients. The surgeons completed a MIE in 206 patients (92.8%). Twelve patients required a thoracotomy, and four patients needed a laparotomy to complete the esophagectomy. Patients were given oral intake by postoperative day 4. Median intensive care stay was 1 day (range, 1 to 30 days), with an average hospital stay of 7 days (range, 3 to 75 days). The mean follow-up was 19 months (range, 1 to 68 months). Dysphagia scores were assigned during follow-up. The mean Health-Related Quality of Life score was 4.6, which represented a normal score. Significant reflux (score of >15) was reported by 4% of the patients. The 30-day operative mortality was 1.4% (three patients). The first death was related to development of pneumonia. The second and third deaths were secondary to a myocardial infarct and pericardial tamponade, respectively. The minor and major complications were 23.9% and 32%, respectively. The most common complications in this series were atrial fibrillation (11.7%) and pleural effusions requiring a chest tube (6.3%). Interestingly, patients with 6-cm conduits had an anastomotic leak rate of 6.1%, and patients with a smaller conduit had a significantly increased leak rate (27.6%; $P < 0.001$). Luketich and associates compared their results with those published in a prospective U.S. Department of Veterans Affairs (VA) database of 1777 patients undergoing esophagectomy.⁴¹ They considered that their 1.3%

mortality rate compared well with the results of the VA study, which reported a 10% perioperative mortality rate. The incidence of complications in the VA database was reported at 50%, with the most frequent complications being pneumonia (21%), respiratory failure (16%), and prolonged ventilatory support (22%). Of the 222 studied cases of MIE, pneumonia was reported in 7.6% and acute respiratory distress syndrome in 5%. It was thought that this suggested an advantage for MIE.

This large series also compared its results with the single-institution report by Swanson and coworkers.¹⁷ In their series of 250 patients undergoing a modified McKeown esophagectomy, the reported 3-year survival rates for their patients assigned to stages I, IIa, IIb, and III were 65%, 41%, 45%, and 17%, respectively. Luketich and associates noted similar survival rates. The higher percentage of induction therapy might be the reason for increased mortality (3.9%) and length of stay (13 days) in the open series compared with that reported by the MIE group. Berrisford and colleagues⁴² found that the operating time for a total MIE decreased significantly ($P < 0.001$) as experience with the procedure increased.

One study evaluated MIE in 41 older adult patients (range, 75 to 89 years).⁴³ In this cohort of patients, the mean intensive care unit (ICU) time was 1 day, and the median hospital stay was 7 days. Major morbidity was reported as 19%, and there was no perioperative mortality.

There are a handful of case-controlled studies. Nguyen and colleagues⁴⁴ reported on a direct comparison of open esophagectomy (OE) and MIE. There was a trend toward shorter operating times, less blood loss, and lower intensive care and hospital stays for this group. However, it has been noted that the MIE group had less advanced stage cancers and the technique was performed by one surgeon, whereas the OE cases were performed by one of four surgeons. Law and coworkers⁴⁵ compared 22 patients who underwent thoracoscopic esophageal mobilization with 63 OE patients. Blood loss was significantly lower in the thoracoscopic group; however, there was no significant difference in morbidity or mortality. Laparoscopically assisted transhiatal surgery in 17 patients was compared with open transhiatal esophagectomy in 14 patients.⁴⁶ This published series also reported shorter operative times and decreased blood loss in the minimally invasive group. In a series of 166 patients, 47 MIE patients were compared with 60 open transthoracic patients and 59 open transhiatal patients.⁸ A lower mortality and reduced morbidity were noted in the MIE group.

The largest series to date comparing minimally invasive surgery with open surgery is that published by Smithers and associates.⁴⁷ This group compared open (114) with thoracoscopically assisted (309) and total minimally invasive (23) esophagectomy. Decreased blood loss in the thoracoscopically assisted (400 mL) and minimally invasive (300 mL) esophagectomy was noted compared with the open surgery (600 mL). Open surgery had shorter operative times (300 minutes) compared with total MIE (330 minutes) but longer times compared with thoracoscopically assisted surgery (285 minutes). MIE patients had the shortest reported hospital stay (11 days),

followed by thoracoscopically assisted patients (13 days) and the open surgical patients (14 days). Stage for stage, there was no difference in overall median or 3-year survival rates among the three groups.

Gemmill and McCulloch⁴⁸ performed a systematic review of minimally invasive surgery for gastric and esophageal surgery spanning 1997 to 2007. Of the 46 articles that met criteria, 23 pertained to esophageal surgery. Most studies reviewed from that period were case series. There were no randomized controlled studies of MIE published during that time. There were 1398 patients in the combined papers. A completely endoscopic surgery was performed in 405 patients; 103 patients had laparoscopic mobilization and a thoracotomy; 561 patients had the reverse, thoracoscopic mobilization and laparotomy. The 30-day in-hospital mortality was 2.3%, and the morbidity was 46.2%. The incidence of anastomotic leak was 7.7%. Respiratory complications at a rate of 13.2% were reported in 1268 patients. Mean operating room time reported for 981 patients was 281 minutes. One group noted that the operating time for a total MIE decreased significantly ($P < 0.001$) as experience with the procedure increased.⁴² Hospital stay was 2 to 195 days, with a mean of 11 days. The average number of lymph nodes retrieved in 607 patients was 17.6. Interestingly, length of stay and overall morbidity rates were not different from those of their open counterparts.

In a recent update Watanabe and colleagues reported acceptable short-term outcomes of video-assisted thoracoscopic esophagectomy for thoracic esophageal cancer in terms of operating time, blood loss, and postoperative complications; these outcomes are comparable with those of conventional open surgery.⁴⁹ With regard to the number of total retrieved mediastinal lymph nodes, most studies have demonstrated that video-assisted thoracoscopic esophagectomy is almost equivalent to open surgery.⁵⁰⁻⁵² Furthermore, a meta-analysis by Dantoc and colleagues emphasized that the number of retrieved lymph nodes was significantly greater with video-assisted thoracoscopic esophagectomy than with OE.⁵³

Uttley and coworkers recently published a systemic review comparing MIE and open surgery. In their review, 28 studies were included. No randomized controlled trials were available. Mean length follow-up was 30 months. Mortality was recorded at 2.4% in the MIE group versus 3.8% in the open group. Recurrence rates were 23.4% in the MIE group and 24.8% in the open group. Tracheal perforation rates were 2.3% in the MIE group versus 6.5% in the open group. Vocal cord injury rates were 12.7% in the MIE group and 9.6% in the open group.⁵⁴

In 2012 Mamidanna and coworkers⁵⁵ published a large United Kingdom population-based study that analyzed the hospital data from April 2005 to March 2010 and included 7502 esophagectomies, 1155 (15.4%) of which were MIE. There was no difference between open and MIE groups, respectively, in 30-day mortality (4.3% vs. 4.0%) and overall morbidity (38.0% vs. 39.2%). However, reintervention rate was higher with MIE compared to open surgery (21% vs. 17.6%; $P = 0.006$). Further editorials pointed to the significant limitations of this population-based study based on an administrative data-

base, as commented by Rice and Blackstone⁵⁶ and Penathur and Luketich.⁵⁷

In 2009, the Eastern Cooperative Oncology Group (ECOG) conducted a prospective, multi-institutional (ECOG 2202) phase II study, evaluating MIE. A total of 106 patients were enrolled. The preliminary results showed that the mortality was low (2%), and at a mean follow-up of 19 months, the estimated 3-year overall survival for the entire cohort was 50%. Stage-specific survival was comparable to that of the open series.⁵⁸

To date, there have been three meta-analyses that examined short-term outcomes of MIE with comparisons with the traditional open technique.⁵⁹⁻⁶¹ There were essentially no marked differences in postoperative major morbidity and mortality rates between the two groups in these meta-analyses. However, Biere and colleagues⁵⁹ demonstrated that there was considerably less incidence of anastomotic leakage in hybrid (thoracoscopy and laparotomy) MIE compared with open surgery. Nagpal and coworkers⁶¹ compared 672 patients for total MIE and hybrid MIE and 612 for open surgery from 12 studies. There were no marked differences in the operating time, number of retrieved lymph nodes, incidence of anastomotic leak, or 30-day mortality between the MIE and OE groups, but MIE had significantly lower blood loss, reduced total morbidity and respiratory complications, and shorter ICU and hospital stay compared with OE.⁶¹ In these meta-analyses, the authors emphasized that several limitations should be considered when referring to the results. Biases may have been introduced by not only the study design but also volume, learning curves, surgeon experience, and publication bias, and it can be difficult to adjust for these factors in meta-analyses.

In terms of cancer outcomes, long-term studies have shown statistical equivalency in long-term survival between MIE and OE. Sgourakis and colleagues⁶⁰ and Dantoc and coworkers⁵³ found no significant differences in 3-year survival rate between the two groups in their meta-analyses.

A randomized controlled trial in this field would be helpful in understanding any benefit that minimally invasive surgery may have over an OE. The time and power that would be required to complete such study are considerable. Surgical skills, specific training in thoracic and upper gastrointestinal surgery, and learning curves are imperative factors to the choice and success of surgery type and are not captured by most available studies. Quality and transparent comparative studies and long-term follow-up of these patients also need to be reported to assess whether smaller access surgery provides equal oncologic outcomes.

A study group in Europe has recently reported the results of the first multicenter randomized controlled trial (TIME trial) that compared MIE and OE.⁶² Patients were randomized to 56 patients in the OE group and 59 to the MIE group. The incidence of pulmonary infection was considerably lower in the MIE group than in the OE group, both within the first 2 weeks after surgery and during the entire hospital stay. MIE patients overall had less operative blood loss, better postoperative quality of life, and shorter hospital stay; however, the 30-day and in-hospital mortality rates did not differ significantly

between the groups. Oncologic parameters, including number of lymph nodes retrieved, did not differ markedly between the two groups. Despite mounting evidence for the safety and benefits of MIE, additional prospective multicenter trials are warranted to further evaluate the long-term outcome of MIE compared with OE.

Left Thoracoabdominal Approach

Indications

The indications for a left thoracoabdominal approach are limited. A distal esophageal tumor beyond 30 to 35 cm in a patient with compromised physiologic status may be a suitable candidate, although some would argue that a transhiatal approach is preferable.

Contraindications

The presence of a tumor that is 30 cm or larger makes an approach from the left chest much more difficult, as the anastomosis must be placed above the aortic arch or in the neck. A distal esophageal peptic stricture is considered by many to be a contraindication to limited distal esophagectomy because gastroesophageal reflux is often a severe problem after distal esophagectomy and placement of the anastomosis low in the chest.

Technique

The left thoracoabdominal approach can be performed in a variety of ways. Isolation with a double-lumen tube is necessary in all the approaches. In the supine position, an upper midline laparotomy can be extended across the costal margin into the left chest through the seventh interspace and the diaphragm taken down in circumferential fashion. This position is least versatile and is generally used only when extension into the chest is unanticipated, as with proximal extension of certain tumors of the gastric cardia. Conversely, the patient may be placed in the full lateral position, and a complete esophagectomy may be performed through a thoracic incision. Abdominal dissection can be performed, although with some difficulty, through an enlarged hiatus or through a circumferential peripheral incision in the diaphragm (Fig. 38-16).

The most versatile thoracoabdominal approach involves placement of the patient in the right lateral decubitus position with the abdomen rolled back 45 degrees. The abdomen is readily accessible for extension of the distal aspect of the thoracotomy across the costal margin and across the rectus muscle. The neck is prepared in the field if extension to the cervical esophagus is a possibility. An incision is made from a point behind the tip of the scapula along the seventh interspace across the costal margin to the middle of the abdomen. The inferior pulmonary ligament is divided with cautery. The esophagus is encircled with a Penrose drain at a point away from the tumor where there is minimal scarring. Complete dissection of the esophagus and all surrounding lymphatic and connective tissue is performed up, including all tissue in between the aorta and

FIGURE 38-16 ■ The left thoracoabdominal approach. The abdomen can be entered through incisions in the diaphragm as delineated by the *dotted lines*. Alternatively, the incision can be taken across the costal margin onto the abdomen and the diaphragm taken down circumferentially from the costal margin incision. (Adapted from Sugarbaker D, DeCamp M, Liptay M: Surgical procedures to resect and replace the esophagus. In Zinner M, Schwartz S, Ellis H, et al, editors: *Maingot's abdominal operations*, Stamford, CT, 1997, Appleton & Lange, pp 885–910.)

the pericardium in the specimen. Dissection proceeds cranially posterior to the left pulmonary veins. Cranial dissection should be performed only to a point approximately 3 cm above the proposed line of transection to preserve blood supply to the anastomosis.

At the diaphragmatic hiatus, a 2-cm rim of diaphragm is included with the specimen. Although it is at times possible to continue dissection of the short gastric vessels and gastrohepatic ligament through the hiatus, exposure is improved by taking the diaphragm down circumferentially at a point 2 to 3 cm away from its insertion on the chest wall. Dissection proceeds from the gastroesophageal junction along the greater curvature, dividing all short gastric vessels. Dissection of the remainder of the gastric conduit is performed as detailed in the section on tri-incisional esophagectomy. Complete dissection of the stomach may not be required if only a very limited portion of distal esophagus is resected. Minimizing dissection at the expense of an entirely tension-free anastomosis, however, is unwise. Kocherization of the duodenum and either pyloroplasty or pyloromyotomy are performed. The conduit is lifted into the chest. The anastomosis can be hand sewn in either a single layer or a double layer. It may also be performed with a large (33-mm) EEA stapler

or as a side-to-side, functional end-to-end anastomosis. A nasogastric tube is positioned before completion of the anastomosis. The conduit should be tacked to the diaphragm and may also be tacked to the adjacent pleura. Buttressing of the anastomosis with available omentum is recommended. The diaphragmatic rim is reattached to the chest wall with interrupted horizontal mattress 0 silk stitches. The costal margin is reattached with a single figure-of-eight wire or heavy Prolene stitch. The abdominal fascia is closed in layers. Before closure of the thoracotomy, a soft drain may be inserted dependently near the anastomosis, and an apical chest tube should be placed, each through separate stab incisions. The thoracotomy incision is closed with #2 Vicryl paracostal sutures, a 0 Vicryl latissimus layer, a 2-0 subdermal layer, and a 3-0 subcuticular stitch.

En Bloc Resection

The long-term survival rate after esophagectomy for esophageal cancer remains approximately 20% despite recent advances in surgical technique, instrumentation, and perioperative care. A large percentage of esophageal cancers manifest with invasion through the esophageal wall (T3) or nodal involvement (N1 or N2). Because radial margins are difficult to assess grossly and even microscopically, it is difficult to ensure complete removal of all invasive and nodal disease. To ensure complete margins and removal of all adjacent nodal tissue, several surgeons have advocated en bloc resection of the esophagus, including all adjacent tissues in the resected specimen. DeMeester and Skinner recommend en bloc esophagectomy for all patients in whom the cardiopulmonary morbidity is not prohibitive.^{63,64} In one of these studies, an FEV₁ of less than 1.5 liters was considered prohibitive. In their nonrandomized series, long-term survival was significantly better in the en bloc resection group versus the conventional approach.

Technique

Although an en bloc resection may be performed through either the left or the right side of the chest, only very distal esophageal tumors may be resected with ease and with adequate margins through a left thoracotomy. Because of the high incidence of postoperative reflux esophagitis, an approach through a right thoracotomy is advised. Entry into the chest is through the right sixth interspace. Two parallel incisions are made in the pleura. An incision is made anteriorly, entering the pericardium, and posteriorly, behind the azygos vein. Intercostal veins draining into the azygos are ligated individually, and the thoracic duct and azygos vein are included in the specimen. Some surgeons do not resect the azygos vein. The left pleura bordering the specimen is harvested and included in the specimen. This plane of dissection is continued cranially to the carina. Above the carina, the margins are limited by the proximity of the trachea anteriorly and the spine posteriorly.

At the hiatus, a 2-cm rim of diaphragm is included with the specimen. In the abdomen, the lesser curvature of the stomach and all nodal tissue along the left gastric

artery are taken. All tissue posterior to the stomach and superior to the border of the pancreas is removed. Nodes along the celiac axis, splenic artery, and superior mesenteric artery are dissected. The gastric tube is then pulled up to the neck for esophageal replacement. DeMeester and his group routinely resect the proximal two thirds of stomach, the greater omentum, and the spleen and its associated nodes. They replace the esophagus with isoperistaltic colon.

Results

Retrospective trials comparing en bloc resection with conventional resection have been associated with heavy selection and staging bias. Patients with poor cardiopulmonary reserve are typically excluded from en bloc resection. Moreover, in conventional resection, the disease is commonly understaged as a limited nodal dissection is performed. Both factors would favor stage per stage improved survival in the en bloc group. In Skinner's series of 128 patients, 78 underwent en bloc resection and the remainder underwent a simpler resection, most through the transthoracic route. Perioperative mortality was similar at 4% to 5% in each group. The incidence of pneumonia, leak, and recurrent nerve injury was similar. Four-year survival in patients assigned to stage III was 37% after en bloc resection and 0% after transhiatal resection. Survival was also better in patients with early-stage disease after en bloc resection compared with non-en bloc resection. In DeMeester's series, 69 patients with gastroesophageal junction tumors were studied. Patients in good health with resectable disease underwent en bloc resection, whereas those in poor health or with apparently unresectable disease underwent a transhiatal resection. Five-year survival was significantly better in the en bloc resection group (41%) compared with the transhiatal group (14%). The complication rate was not mentioned in this study.

Three-Field Lymph Node Dissection

Three-field lymph node dissection is a term applied to the addition of a cervical nodal dissection to the traditional thoracic and abdominal nodal dissections that are performed during esophagectomy for cancer. Ten percent to 30% of patients with lower esophageal cancers have cancers that spread to cervical nodal areas, and the same is true of celiac nodes in patients with cervical esophageal cancers.⁶⁵⁻⁶⁷ Proponents of this technique argue that cervical nodes should be considered resectable even in patients with lower esophageal cancers and should routinely be resected with the specimen.

The abdominal and thoracic phases of the operation are almost identical to those performed during a tri-incisional en bloc resection of the esophagus. Attention is paid to dissection of the recurrent nerve lymph node chain in the thorax. The neck is incised bilaterally with a U-shaped incision. The sternocleidomastoid muscles are divided. The deep cervical nodes deep and lateral to the jugular vein are dissected, dissection of the recurrent nerve nodes in the neck is continued, and the supraclavicular nodes are also removed.

In experienced hands, the incidence of recurrent nerve injury is no higher than with any other esophagectomy requiring a cervical incision. Altorki and Skinner⁶⁶ described a recurrent nerve injury rate of 6%. In their series, there was only one perioperative death, which was from the only case of pneumonia. Although the benefit of three-field lymph node dissections is not clear, several older studies suggested an improved survival.^{65,68} A Japanese study by Ando and coworkers⁶⁷ and a U.S. study by Altorki and coworkers⁶⁹ showed 5-year survival rates in the range of 40% to 50% after en bloc esophagectomy with three-field lymph node dissection. The study of Ando and coworkers was limited to patients with squamous carcinoma; the U.S. study included patients with adenocarcinoma and squamous cell carcinoma. The perioperative mortality rate was 5% to 8% in both studies. There was a 20% to 25% pulmonary complication rate in each study. The recurrent nerve injury rate was 9% in the study of Altorki and coworkers; it was not mentioned in the study by Ando and coworkers. In these selected studies, the perioperative morbidity rate is comparable to that in other studies, although perioperative mortality in the Ando study is higher than the quoted rate of 3% to 4% from several large academic studies of esophagectomy without en bloc or three-field dissections.^{17,70} Long-term survival is impressive, although it is not clear if selection factors or differences in tumor biology between the Japanese and U.S. populations might account for some of the difference.

Surgical Variations

Minimally Invasive Esophagectomy in the Prone Position. A number of surgeons have advocated thoracoscopic mobilization of the esophagus in prone position as a potentially ergonomic approach with the advantage of less pulmonary morbidity. Noshiro and colleagues published their experience with prone positioning during MIE.⁷¹ Compared with left lateral decubitus positioning, prone positioning was associated with lower blood loss and better exposure of the operative field around the left recurrent laryngeal nerve. However, recurrent laryngeal nerve injury rates were not significantly different between prone and left lateral decubitus-positioned patients.

Palanivelu and coworkers published their series of 130 patients who underwent MIE with thoracoscopic esophageal mobilization in prone position using a right prone posterior approach. This approach allows left lung ventilation with possible intermittent ventilation of the right lung. Mean operative time was 220 minutes (range 160 to 450 minutes) and median ICU stay was 1 day (range, 1 to 32 days). Postoperative pneumonia rate was only 1.54%. The authors have advocated prone positioning, allowing partial intermittent right lung ventilation and possibly prevention of postoperative atelectasis.⁷² Surgeons who advocate the prone position argue that functional residual capacity and ventilation-perfusion matching, ventilation in the dorsal lung areas, tidal volume in relation to modulated chest wall movement, and alveolar recruitment are improved in prone, compared with supine, position. Further comparison of the left lateral decubitus position with the prone position has

recently been published.⁷³ Twelve articles reporting the outcomes following prone thoracoscopic esophagectomy were analyzed. All 12 studies were nonrandomized single-center prospective or retrospective studies of which four compared the technique with traditional minimally invasive surgery. The prone esophagectomy has been demonstrated as being both feasible and safe; however, there is no convincing evidence that it is superior to other forms of esophageal surgery. Additional comparison studies are needed to confirm the superiority of the prone position over the left lateral decubitus position in MIE.

Robotic Esophagectomy. Robot-assisted esophagectomies have been described with a wide variety of reported outcomes. Recent review articles of robotic-assisted MIE have concluded that the data regarding robotic-assisted MIE indicate safety, feasibility, and equivalent outcomes compared with open surgery or MIE. However, there are no available data to suggest improved outcomes with robotic-assisted MIE in terms of operative morbidity, pain, length of stay, operative time, or total costs.⁷⁴

Weksler and colleagues performed a retrospective comparison of 11 patients who underwent thoracoscopic robot-assisted MIE versus 26 who underwent MIE. No significant differences were seen in operative time, blood loss, postoperative complications, or length of stay.⁷⁵

Galvani and coworkers at the University of Illinois reported on 18 patients who underwent robotic-assisted transhiatal esophagectomy. Although anastomotic leak occurred in 6 (33%) patients, other parameters such as mean estimated blood loss of 54 mL and low cardiopulmonary morbidity (1 pleural effusion and 2 cases of atrial fibrillation) suggested safety and feasibility of robotic-assisted transhiatal esophagectomy.⁷⁶

Rusch and associates⁷⁷ recently reported their series of 21 patients who underwent four-arm robotic esophagectomy (17 with the Ivor Lewis technique and 4 with the McKeown technique). The median operative time was 556 minutes (range, 395 to 807 minutes); this reduced to 414 minutes (range, 405 to 543 minutes) for the last 5 cases in the series. The median length of hospital stay was 10 days (range, 7 to 70 days). The median number of lymph nodes resected was 20 (range, 10 to 49). Five (24%) patients were converted to open procedures. Five patients (24%) had major complications. One (5%) died of complications on postoperative day 70, and 3 (14%) had clinically significant anastomotic leaks.

The ROBOT trial, currently under way, is the first randomized controlled trial designed to compare robotic esophagectomy with open transthoracic esophagectomy; the trial started in January 2012.⁷⁸ Until further results are available, the superiority of robot-assisted thoracoscopic esophagectomy compared with conventional thoracoscopic esophagectomy without robot assistance should be carefully evaluated.

Prognostic Significance of Number of Lymph Nodes Resected

Any assessment of the benefits of extended lymphadenectomy must consider the potential morbidity of the procedure. Until an improvement in survival can be

demonstrated, the potential morbidity of this procedure has heightened significance.

Rizk and colleagues⁷⁹ reported the prognostic significance of the number of involved lymph nodes in patients with esophageal cancer. This retrospective review examined the records of 336 patients operated on between January 1996 and September 2003. The patients studied received surgery as their only treatment. Recursive partitioning analysis using lymph nodes as a variable in addition to T, N, and M status showed that the presence of more than four positive lymph nodes was the most important prognostic factor. This group also reported that the likelihood of finding positive N1 nodes increased when more than 18 nodes were present in the specimen. They concluded that when the appropriate number of lymph nodes is obtained, depth of invasion of the tumor is not a prognostic indicator because survival assessment will be based on lymph node involvement. Since this landmark article was published, several published articles have confirmed that the number of lymph nodes removed has prognostic significance.

Greenstein and associates⁸⁰ evaluated 972 patients in the SEER cancer registry treated with an esophagectomy for esophageal malignant disease diagnosed between 1988 and 2003. Interestingly, on multivariate regression controlling for age, race or ethnicity, sex, histology, tumor status, and postoperative radiotherapy, patients with pathologic node-negative disease in 18 lymph nodes or more were found to have a higher disease-specific survival.

Another group, also using the SEER database, reported that the number of lymph nodes removed is an independent predictor of survival after an esophagectomy for malignant disease.⁸¹ Of the 2303 patients studied, 1700 patients had an esophagectomy with a thoracotomy and 603 patients had an esophagectomy without a thoracotomy. The Cox regression analysis showed that the number of lymph nodes removed was an independent factor for survival. They concluded that it was necessary to have 23 to 29 lymph nodes in the specimen to provide optimal survival.

Altorki and coworkers⁸² retrospectively reviewed their single-institution experience with 264 patients with esophageal cancer treated with esophagectomy between 1988 and 2006. They also concluded that increased nodal resection is an independent factor that favorably influences survival. The survival advantage is most apparent in the subgroup of patients with distal esophageal cancers with limited lymph nodes metastasis who have had a more extensive lymph node dissection. A recent review concluded that a radical lymph node dissection is beneficial and provides better survival advantage in patients with resectable esophageal cancer.⁸³

Techniques of Alternative Conduits: Colon and Jejunum

Colon

Indications. The stomach is the preferred conduit for esophageal replacement. It has several advantages over the colon, including a reliable blood supply that is usually

free of atherosclerotic disease, a low intraluminal bacterial burden, and the need for only a single anastomosis. In those cases when the stomach is not available, usually because of previous abdominal or gastric surgery or involvement of the stomach with tumor, the colon becomes the preferred conduit. The left colon differs from the right in that its lumen is smaller and more closely approximates that of the esophagus. Its usable length is usually greater than that of the right colon. The vascular anatomy on the left is more consistent than on the right; however, involvement by atherosclerotic disease of the inferior mesenteric artery is more common than in any other mesenteric vessel. In general, isoperistaltic orientation is preferred and can be achieved without tension.

Contraindications. Intrinsic disease of the colon by neoplasia, stricture, or extensive diverticulosis precludes its use as an esophageal replacement. In addition, prior abdominal surgery that may have interrupted either the arterial blood supply or the venous drainage of the colon may render a segment of the colon unusable. The inferior mesenteric vein drains into the splenic vein, and prior severe pancreatitis or other causes of splenic vein thrombosis may render the left colon unusable as a conduit because of inferior mesenteric vein thrombosis.

Preparation. The patient should be screened for cardiopulmonary disease as for esophagectomy with gastric reconstruction. In addition, preoperative mesenteric angiography should be performed for any patient older than 40 years or otherwise with risk factors for atherosclerotic disease. A barium enema study or colonoscopy should be performed to rule out a coexistent neoplasia or extensive diverticular disease. Mechanical and antibiotic bowel preparation is administered.

Left Colon

As stated previously, the left colon has several advantages over the right, including a longer length, a less vascular anatomic variation, and a caliber more similar to that of the esophagus. A midline laparotomy is performed, and the abdomen is explored. The peritoneal attachments of the left colon to the retroperitoneum are divided along the white line of Toldt. The length of the conduit that is needed should be estimated by passing an umbilical tape from the proposed proximal line of transection of the esophagus through the proposed route of placement of the conduit to the point of proposed anastomosis to the stomach. The umbilical tape can then be used to measure an appropriate length of colon.

The vessels supplying the left colon are visualized by transillumination. The middle colic artery should be test clamped with a noncrushing bulldog clamp. A palpable pulse should still be present in the marginal artery. If there is any question, a Doppler probe may be used, or the bulldog clamp should be left in place and the conduit inspected for adequate perfusion. Only after it is determined that the conduit is of satisfactory quality should the esophagectomy be completed. The left colon should then be prepared. The omentum is separated from the

left colon and splenic flexure that is to be used as a conduit. The middle colic artery is divided, and the mesentery is divided near its root, away from the marginal artery of Drummond (Fig. 38-17). The colon is reanastomosed, and the mesenteric defect is closed.

Either the proximal or the distal anastomosis may be done first; however, we believe that construction of the proximal anastomosis first allows better determination of conduit length and ensures that the conduit will sit properly in the neck. The proximal end of the conduit may be drawn up into the neck by use of an atraumatic method,

FIGURE 38-17 ■ The mesentery of the mobilized colon is transilluminated, revealing the mesenteric vessels. The *dotted lines* are the lines of division for a conduit based on the left colic artery. (Adapted from Sugarbaker D, DeCamp M, Liptay M: Surgical procedures to resect and replace the esophagus. In Zinner M, Schwartz S, Ellis H, et al, editors: *Maingot's abdominal operations*, Stamford, CT, 1997, Appleton & Lange, pp 885–910.)

such as an endoscopic camera bag (see tri-incisional technique). The posterior mediastinal (in situ) route is preferred as this is the shortest route between the stomach and esophagus (Fig. 38-18). If the posterior mediastinal route is unavailable because of prior infection or scarring, as occurs with a prior gastric conduit leak, the substernal or transpleural route is an option. These routes, however, result in more conduit angulation and may impair emptying. Routine resection of the manubrium or a portion of the manubrium is necessary to prevent obstruction and to allow adequate space for the colon if the substernal route is used. Excess length is taken out of the conduit. If there is significant excess length, the proximal end may be trimmed as needed. The proximal anastomosis is typically constructed with a single- or two-layer hand-sewn anastomosis of the end of the esophagus to the side of the antimesenteric taenia. A stapled technique may also be used as detailed in the section on tri-incisional esophagectomy. The anastomosis should be constructed over a nasogastric tube with its tip positioned in the center of the stomach. The conduit should be monitored for arterial insufficiency or venous engorgement. The gastrocolic anastomosis is performed with a large EEA stapler or in a side-to-side functional end-to-end stapled manner. Before closure, the conduit should be sutured to the crus to prevent migration of the colon into the chest or herniation of abdominal viscera into the chest.

Right Colon

Various conditions may make the left colon unusable as a conduit. These include extensive diverticular disease, stricture secondary to ischemia or prior diverticular infection, atherosclerotic occlusion of the inferior mesenteric artery, and splenic vein thrombosis with thrombosis of the inferior mesenteric vein. The right colon is an acceptable conduit and will readily reach the esophagus in the neck.

The right colon is inspected for any disease, and its retroperitoneal attachments are lysed. The mesentery of the right colon may be transilluminated, showing the ileocolic, right colic, marginal, and middle colic arteries.

FIGURE 38-18 ■ The posterior mediastinal (in situ) route is the shortest route between the stomach and esophagus. (Adapted from Sugarbaker D, DeCamp M, Liptay M: Surgical procedures to resect and replace the esophagus. In Zinner M, Schwartz S, Ellis H, et al, editors: *Maingot's abdominal operations*, Stamford, CT, 1997, Appleton & Lange, pp 885–910.)

Soft clamps are placed on the ileocolic and right colic arteries, and the right colon is inspected for adequate perfusion through the marginal artery. The right colon is then harvested, leaving the marginal artery intact. An appendectomy is performed. Whether the ileocecal valve and short segment of ileum should be included in the conduit for esophageal anastomosis is controversial. The ileum provides a better size match for anastomosis with the esophagus, and in theory, the ileocecal valve should guard against reflux in the neck. Opponents argue that despite the size mismatch, a hand-sewn anastomosis of the end of the esophagus to the side of the colon is easy, reflux esophagitis is rare high in the neck, and the ileocecal valve may contribute to antegrade obstruction.

Appropriate lengths of right colon are divided with a GIA 75-mm stapler, and the colocolonic anastomosis is performed. From the surgeon's perspective, the right colon conduit is rotated counterclockwise, and the proximal end is drawn up into the neck in atraumatic fashion. The proximal anastomosis is created most easily by a single-layer end of esophagus to the side of the colon along a taenia. Excess length is brought out into the abdomen, and the conduit is tacked to the hiatus. At this point, excess length in the distal conduit can be managed by excising colon at the end of the vascular conduit. The cologastric anastomosis is usually constructed with either EEA staplers or a side-to-side stapled technique. The colon may be brought into the anterior aspect or posterior aspect of the stomach.

Jejunum

Indications. Jejunum may be used to replace a portion of the esophagus as a free graft, pedicled graft, or Roux-en-Y replacement.^{84,85} Replacement of the esophagus with jejunum is indicated when the stomach is not available because of prior surgery or intrinsic disease. When limited distal esophagectomy is planned, jejunum or colon is preferred to stomach as these two conduits are more resistant to the effects of gastroesophageal reflux. Replacement of a distal esophageal peptic stricture should be performed with colon or jejunum in preference to stomach. Interposition of an isoperistaltic segment of intestine is preferable to gastric pull-up, which has a very high incidence of recurrent severe reflux. Free jejunal graft is indicated in limited reconstruction of the cervical esophagus. Roux-en-Y jejunal replacement may be used to replace the stomach and distal esophagus after total gastrectomy including distal esophagectomy.

Contraindications. Intrinsic disease of the small bowel, whether it is a result of inflammatory bowel disease or previous surgery, may prevent use of the small bowel as a conduit. In general, total esophageal replacement cannot be accomplished with jejunum alone because the length is insufficient to reach the neck.

Preparation. Although mechanical bowel preparation is not necessary for jejunal interposition, it is advisable so that colon is available if the jejunum is found to be unacceptable as a conduit or if the blood supply to the jejunum is damaged during harvest, rendering it unusable as a

conduit. Antibiotics (a cephalosporin and an anaerobic antibiotic) should be administered preoperatively.

Roux-en-Y Replacement. Roux-en-Y replacement (Fig. 38-19) may be used for reconstruction after total gastrectomy and distal esophageal resection as indicated in proximal gastric tumors or for esophageal resection into the upper chest. On occasion, a Roux-en-Y replacement may reach the neck, but this is variable, and unlike the stomach, it will not reliably reach the cervical esophagus. When it is used after total gastrectomy, jejunum is divided approximately 20 to 30 cm beyond the ligament of Treitz. The jejunum is elevated outside the abdomen, and the vascular arcade is transilluminated. The proposed point of division is identified, and the line of division of the mesentery is also identified along with the proposed division of several vessels of the mesentery, which will allow movement of the jejunum up into the chest. The proposed feeder vessel is identified and preserved. The serosal surface of the mesentery is scored, and the vessels to be transected are clamped with a soft bulldog clamp. The conduit is observed for several minutes for evidence of ischemia or congestion. By this technique, 60 cm of jejunal conduit can be mobilized. A hole in the transverse mesocolon is made to the left of the middle colic vessels large enough for the jejunum and its mesentery to pass through. For replacement after total gastrectomy, the proximal anastomosis is to the very distal esophagus in the upper abdomen. If distal esophagectomy is also performed as for a malignant lesion of the cardia extending

FIGURE 38-19 ■ Roux-en-Y replacement with jejunum is useful for reconstruction after esophagectomy with gastrectomy, as with proximal gastric tumors.

to the gastroesophageal junction, the abdominal incision must be brought across the costal margin into the left sixth or seventh interspace. If, after division of the esophagus and mobilization of the Roux-en-Y limb into the lower chest, additional length of jejunum is needed, the next vessel in the mesenteric arcade is test clamped and then divided.

The esophagojejunal anastomosis can be performed by stapled or hand-sewn techniques. The stapled anastomosis is most easily performed with an EEA stapler. Ideally, a size 33-mm EEA stapler should be used to protect against the development of strictures. The distal esophagus may be gently dilated with a lubricated dilator. A full-thickness 2-0 Prolene suture is used to create a purse-string in the distal esophagus. The shaft of the EEA stapler can be introduced through the stapled end of the proximal jejunum. Care must be taken not to occlude the ongoing lumen of the jejunum with the stapler. Two full-thickness anastomotic doughnuts should be verified. After removal of the EEA stapler, the jejunal end can be closed with a TA 60-mm stapler. A hand-sewn anastomosis in two layers may also be performed. The outer layer is seromuscular on the jejunum to muscular esophagus with 3-0 silk, and the inner layer is full thickness with interrupted 3-0 or 4-0 chromic gut.

The jejunum should be tacked to the hiatus at several points with interrupted silk sutures. This prevents herniation of abdominal contents into the chest and limits tension on the esophagojejunal anastomosis. Similarly, the defect in the colonic mesentery should be closed to prevent an internal hernia. The distal anastomosis can be hand sewn or performed by a side-to-side functional end-to-end stapled technique.

Pediced Jejunal Interposition. A left thoracoabdominal incision is used with a left seventh interspace incision extended across the costal margin and across the rectus muscle. As with the harvest of a Roux-en-Y loop, the jejunum is transilluminated, and an appropriate length of jejunum is selected from a point 20 cm distal to the ligament of Treitz. A single large vessel is used as a feeding vessel for the conduit. The jejunum is transected proximally and distally with a GIA stapler, and the mesentery is divided down each side to the origin of the vessel. The remaining jejunum is reconnected by a side-to-side functional end-to-end stapled technique. The pediced jejunum is tunneled through the mesocolon and brought into the left chest. The proximal anastomosis is constructed like the Roux-en-Y esophagojejunal anastomosis. The jejunogastric anastomosis may be hand sewn in two layers or stapled with an EEA stapler (Fig. 38-20).

Free Jejunal Interposition. Free jejunal graft may reach portions of the upper esophagus that pediced grafts may not. It is not clear whether the use of a short jejunal interposition is preferable to total esophageal replacement with a normal gastric conduit. The use of jejunum carries a lower incidence of gastroesophageal reflux; however, the increased risk of life-threatening graft ischemia and necrosis is significant. Moreover, two anastomoses are required, increasing the risk of anastomotic leak.

FIGURE 38-20 ■ Pediced jejunum is ideally suited for distal esophageal replacement. An appropriate length of jejunum is harvested beginning 20 cm beyond the ligament of Treitz.

As with the pediced jejunal graft, a short segment of jejunum is chosen for harvest. A left cervical incision is made, and the esophagus and carotid and jugular vessels are isolated. Soon after division of the jejunal vessels with a scalpel, the artery and vein are flushed with heparinized saline. The proximal hand-sewn anastomosis is constructed first, an operating microscope and fine 9-0 or 10-0 suture are used to anastomose the jejunal vessels to the carotid and jugular vessels, and the distal anastomosis is then constructed (Fig. 38-21). The graft is covered with a meshed split-thickness skin graft to monitor graft viability in the postoperative period.

CONSIDERATIONS IN ESOPHAGEAL RESECTION

Perioperative Mortality

Historically, esophagectomy has been associated with the highest perioperative mortality rate of any commonly performed resection. The combination of a long

FIGURE 38-21 ■ Free jejunal interposition may be used where pedicled graft will not reach, such as in the proximal esophagus. The arterial and venous supplies are anastomosed to the carotid and jugular vessels under the operating microscope. A split-thickness skin graft covers the graft to allow inspection of graft viability in the perioperative period.

operation traversing three body compartments in an older, potentially malnourished adult with the potential for overwhelming mediastinal sepsis has produced perioperative mortality rates that were initially quoted at 15% to 40%.^{86,87} Reports published after 1980 showed improvement in the mortality rates to approximately 15%, with a large meta-analysis of papers published between 1986 and 1996 showing mortality rates averaging 6% to 10%.^{23,88} Several large academic centers have published large series with mortality rates ranging from 3% to 4%.^{17,70,89}

A relationship between esophagectomy and hospital volume and outcome has been reported, beginning in the late 1970s.⁹⁰ In a review of this topic for the journal *Thoracic Surgery Clinics*, Chang and Birkmeyer⁹¹ noted 11 of 12 studies publishing statistically significant volume-outcome relationships pertaining to esophagectomy. One of the authors had used the Medicare database to produce the largest study to date evaluating mortality and esophagectomy.⁹² His analysis showed that 6337 patients underwent an esophagectomy at 1575 hospitals. Low-volume hospitals were defined as those with fewer than two operations per year. Higher volume hospitals performed more than 19 such operations per year. The in-hospital mortality rate of the high-volume center was considerably lower (8.1%) than that of the low-volume hospital (23.1%). A second report from this same group examined surgeon volume and outcomes.⁹³ Using the Medicare database from 1998 to 1999, they reported that surgical outcome with regard to operative mortality was inversely related to surgeon volume. They found the surgeon volume and hospital volume to be independent factors in outcomes. A low-volume surgeon at a high-volume center has higher mortality rates than does a high-volume surgeon at a high-volume center. The application of this information to policy and certification of hospitals and surgeons for this highly technical operation is beyond the scope of this chapter.

Several studies have identified age as a risk factor for increased morbidity and mortality after an esophagectomy. An analysis of the Nationwide Inpatient Sample

database revealed a 19.9% perioperative mortality rate in octogenarians after esophagectomy. This is significantly different from the 8.8% perioperative mortality after similar surgery in patients 65 to 69 years old ($P < 0.0001$).⁹⁴ It is clear that advances in surgical technique, anesthesia, and intensive care have markedly improved the safety of esophagectomy during the past several decades. In older series, the greatest contributor to perioperative mortality was intrathoracic sepsis caused by either an anastomotic or a conduit leak. The mortality rate from a clinically overt intrathoracic leak may be greater than 50%.⁹⁵ Aggressive, early management of an intrathoracic esophageal leak is essential in limiting its possible fatal effects.

In the more recent, larger series published with mortality rates less than 5%, the most common cause of perioperative death is not conduit leak; rather, it is pulmonary causes: respiratory insufficiency, pneumonia, or pulmonary embolus.^{17,70,89} The combination of a low incidence of leak with early, aggressive management has made the intrathoracic enteric leak less of a factor in perioperative mortality.

Early Perioperative Complications

Anastomotic Leak

The incidence of intrathoracic leak after Ivor Lewis esophagectomy is typically 5% to 10%.^{19,23} The incidence of leak after a cervical anastomosis is higher, generally in the 10% to 15% range.^{23,70} Older studies have quoted cervical leak rates at 25% to 26%, whereas a recent large study described a leak rate of 8%.^{17,87,96} A retrospective evaluation of anastomotic leaks revealed that albumin level below 3 g/dL, positive margins, and cervical anastomosis were risk factors for anastomotic leak after esophagectomy.⁹⁶ Several factors are believed to be responsible for the increased incidence of leak in the cervical position. The increase in length needed may cause increased tension on the anastomosis. Blood supply to the anastomosis may be compromised because it is

farther away from the origin of the gastroepiploic artery, and arterial inflow and venous drainage may be compromised by a tight thoracic inlet. In a randomized trial of hand-sewn versus stapled anastomosis in 102 patients undergoing Ivor Lewis esophagectomy, no significant difference was seen in the incidence of leaks between the two groups. The incidence of leak was 5% after a single hand-sewn monofilament anastomosis and 2% after stapled anastomosis.⁹⁷

The Mayo Clinic published its retrospective review of stapled versus hand-sewn esophagogastric anastomosis.⁹⁸ Hand-sewn esophagogastric anastomosis was performed at the Mayo Clinic only until 2002, when stapling devices were used to resume gastrointestinal continuity. Around this time, 280 patients who underwent an esophagectomy by the transhiatal, transthoracic, or tri-incisional approach were evaluated. It was found that the method of stapling of the anastomosis was safe and associated with a lower leak rate and need for dilation compared with the hand-sewn group. Clearly, the incidence of leak after hand-sewn anastomosis is more operator dependent than with stapled anastomosis, and the reproducibility of the stapled anastomosis is its main advantage.

An intrathoracic leak is a life-threatening event that usually requires immediate operative intervention. Although the mortality rate from this complication has been lowered at large centers during the past few decades, the cost in ICU and hospital stay and delayed recovery remains high. The intervention required ranges from repair and drainage of a limited leak, to placement of a T tube, to complete diversion by split fistula and reduction of viable gastric conduit into the abdomen. The more critically ill the patient is as a result of the leak, the more aggressive and definitive the treatment required. In rare cases (a clinically silent, small contained leak draining back into the conduit not near vital structures such as the trachea or aorta), such a leak may be treated conservatively with antibiotics and maintenance of strict NPO status.

Historically, a thoracic leak is associated with a higher mortality rate than a cervical anastomotic leak is. With adequate drainage, some authors are questioning this belief.^{99,100} As stent technology has developed, there have been reports of its use for control of an anastomotic leak.¹⁰¹⁻¹⁰⁴ Siewert and coworkers¹⁰¹ inserted a self-expanding covered metal stent at the site of intrathoracic leak in 10 patients. Radiologic methods confirmed closure of anastomotic leak in all but one patient. In this patient the stent was adjusted, and closure of the leak was confirmed. Stent migration requiring new stents and adjustment occurred in four patients. The authors found that in all but one patient, complete leak closure was achieved. Two patients died of reasons not related to stent placement, but further details were missing from the report. Stent technology continues to develop new indications for its use; however, indications for control of an anastomotic leak have not been confirmed by large randomized trials.

Leak after a cervical anastomosis, although more frequent, is uncommonly a life-threatening event. Older series have described mortality from a cervical leak as high as 20%, although recent series have described mortality rates that are much lower.^{17,95} Cervical anastomotic leak occurs, in general, later than intrathoracic leaks do,

with many diagnosed only on routine postoperative barium swallow study or on commencement of oral feeds after a normal barium swallow study.¹⁰⁵ Patients with cervical leaks can develop low-grade fevers, localized redness, or wound discharge. Treatment usually entails limited opening of the neck incision and placement of a wick. Larger leaks resulting from anastomotic necrosis may be treated with a Silastic stent or T tube. Leaks into the chest after cervical anastomosis, resulting from either retraction of the anastomosis into the chest or dependent drainage of enteric contents into the chest, must be treated in the same manner as any intrathoracic leak. The main long-term sequela of a cervical anastomotic leak without signs of systemic sepsis is an increased incidence of delayed stricture formation.

Respiratory Complications

Pneumonia, atelectasis, and respiratory failure, in the modern era, are probably the most serious complications after esophagectomy given their relatively high incidence and potentially life-threatening consequences. The incidence of pneumonia after esophagectomy ranges from 2% to 47%.^{31,95} Respiratory failure after esophagectomy occurs in 4% of patients.²³ The assumption that avoidance of thoracotomy results in fewer pulmonary complications than with a transthoracic esophagectomy has not conclusively been supported by the literature. In the randomized trial of Goldmine and associates²⁸ comparing transhiatal with Ivor Lewis esophagectomy, the incidence of pneumonia was 20% for both groups. In the randomized trial of Chu and coworkers³⁹ comparing transhiatal with Ivor Lewis esophagectomy in 39 patients, the incidence of pneumonia was 10% after transhiatal and 0% after Ivor Lewis resection (no significant difference). A European randomized trial comparing transhiatal with en bloc tri-incisional esophagectomy showed a difference in the rate of pulmonary complications (pneumonia or lobar atelectasis) in the tri-incisional (57%) versus the transhiatal group (27%).³² The unusually high incidence of pulmonary complications in both groups of this series should be questioned. Typically, rates of pulmonary complications are in the 20% range.²⁴ Previous series involving en bloc resections have described pneumonia rates of 5%.⁶³

A muscle-sparing, limited thoracotomy, epidural anesthesia, and early ambulation are essential in limiting post-thoracotomy respiratory complications. A multivariate analysis showed that age and decreased FEV₁ are predictive of postoperative respiratory failure.¹⁰⁶ Age, preoperative chemoradiation, and decreased FEV₁ have also been identified as risk factors for respiratory compromise after an esophagectomy.¹⁰⁷

As discussed in the earlier section on MIE, many proponents of smaller access surgery have reported fewer pulmonary complications with this approach to an esophagectomy.

Recurrent Laryngeal Nerve Injury

The incidence of recurrent nerve injury and vocal cord dysfunction after esophagectomy is higher with a cervical anastomosis than with an intrathoracic anastomosis.

Malfunction of a single vocal cord, although seemingly a minor complication resulting in hoarseness, can lead to a series of life-threatening complications if it is not recognized early and treated. The lack of vocal cord apposition makes an effective cough and clearance of pulmonary secretions difficult. This is exacerbated by the loss of airway protection during swallowing and repeated episodes of overt aspiration or microaspiration.

As expected, the incidence of recurrent nerve injury is higher with a cervical anastomosis (11%) than with an intrathoracic anastomosis (5%).²³ In the right thorax, the recurrent nerve may be injured by traction on the vagus nerves or by cautery near the nerve as it recurs around the subclavian artery. In addition, a neck dissection may result in direct injury to the recurrent nerves as the esophagus is dissected away from the tracheoesophageal groove. In the neck, dissection must be performed immediately against the esophagus, with care taken to recognize and avoid the recurrent nerve. Dissection close to the recurrent nerves does not necessarily place them at risk; one series of three-field lymph node dissection with direct dissection of all lymph nodes adjacent to both recurrent nerves resulted in a recurrent nerve injury rate of only 6%.⁶⁶

Early recognition and treatment of a recurrent nerve injury (in itself a non-life-threatening condition unless both cords are simultaneously injured) are essential in preventing the potentially lethal complications of aspiration and pneumonia. Any patient who presents with hoarseness and an ineffective cough after esophagectomy should undergo fiberoptic laryngoscopy. Unilateral paralyzed vocal cords should be medialized by either injection or prosthesis implantation. Early intervention can lead to a low incidence of pulmonary complications.¹⁷

Bleeding

The incidence of bleeding after esophagectomy is approximately 5% and does not vary according to the techniques used.²³ In a meta-analysis, average blood loss was slightly higher for the transthoracic approach, averaging 1000 mL, than for the transhiatal approach, averaging 728 mL.²⁴ Anticoagulants and antiplatelet agents should be stopped before esophagectomy is performed. Low-dose subcutaneous heparin does not increase the incidence of bleeding after esophagectomy. Direct arterial branches from the aorta to the esophagus usually found in the lower thorax should be clipped, not simply cauterized. Larger arteries supplying the esophagus branch into a fine plexus of arterioles at a point 1 to 2 cm away from the esophagus. If blunt dissection of the esophagus is used, it should be kept immediately adjacent to the esophagus with disruption of only the smaller arterioles.

Chyle Leak

The thoracic duct drains the cisterna chyli in the abdomen beginning at the L2 level. It enters the chest through the aortic hiatus and ascends through the right chest behind the esophagus along the vertebral bodies between the azygos vein and the aorta. On occasion, more than one

channel exists in the lower chest at the level of the hiatus. At approximately the T6 level, it crosses to the left side behind the aorta and ascends along the left side of the esophagus posterior to the left subclavian artery. Above the clavicle, the duct descends behind the carotid sheath and anterior to the anterior scalene muscle and phrenic nerve to empty into the junction of the left internal jugular and subclavian vein. The duct can be injured at any point along dissection of the esophagus. The incidence of chyle leak after esophagectomy ranges from 2% to 10%.^{23,31} The incidence is higher after transthoracic resection, probably as a result of an extended radial dissection of the esophagus and associated nodal tissue. Prophylactic mass ligation of the duct at the hiatus may help decrease the incidence of postoperative leak. If chest tube output is 1000 mL/day or more 48 hours after esophagectomy, chylothorax should be suspected. Diagnosis can be difficult because the classic milky appearance of chyle is apparent only in a fed patient. Gram stain will exclude polymorphonuclear cells. Fluid should be sent for determination of triglyceride level, cholesterol level, and cell count. A triglyceride level of greater than 1 mmol/liter is highly suggestive of a chyle leak, as is a lymphocyte count of greater than 90%. A cholesterol-to-triglyceride ratio of less than 1 and confirmation of chylomicrons on electrophoresis have also been suggested to be diagnostic of a chyle leak. Perhaps the best and simplest test is feeding cream at 30 mL/hr through the J tube for 3 to 4 hours, watching for a change from serous pleural fluid to a milky fluid.

There is no role for conservative management of a high-output chyle leak after esophagectomy. Continued loss of lymphocytes, protein, fats, and fluid at a rate of 1 liter/day or more in a malnourished patient healing from a major operation invites disaster. Once the diagnosis is confirmed, or even if the diagnosis is highly suspected, the patient should be brought back to the operating room for ligation of the duct at the level of the hiatus. Cream should be instilled through the J tube for several hours before reoperation. The approach to ligation of the duct should be through a right thoracotomy or thoracoscopy. The exact site of injury can often be located after the patient has been given cream enterally. It may be repaired with pledgeted 4-0 or 5-0 monofilament sutures. If there is any doubt about the integrity of the repair, the duct should be mass ligated at the level of the hiatus. The pleura is incised, and a 0 silk mass ligature is used to encompass all tissue between the azygos vein and aorta along the spine. A pledgeted suture should be used if tissue integrity is poor. A careful search to confirm cessation of the leak should be performed before closure.

Noninvasive methods for closure of thoracic duct leaks have been proposed. The thoracic duct can be cannulated percutaneously by puncture into the cisterna chyli and embolized with coils or fibrin glue. In a trial of 42 patients (9 of whom were postesophagectomy patients), the thoracic duct could be embolized in 26 patients, and 16 of these were cured.¹⁰⁸ This technology is in evolution and at this point should be reserved for complex patients for whom surgical repair has failed or for patients who are not candidates for surgical repair.

Cardiovascular Morbidity

Perioperative arrhythmias after esophagectomies have a reported incidence of 20% to 60%.¹⁰⁹⁻¹¹⁴ The development of new-onset perioperative atrial fibrillation has been linked to anastomotic leaks and pulmonary complications.¹¹¹ Although arrhythmias can be treated effectively with calcium channel blockers and beta blockers,¹¹⁵ patients given prophylactic digoxin did not have a reduced incidence of cardiac arrhythmias.¹¹⁰

The incidence of myocardial infarction after esophageal resection is 1% to 2%.¹⁰⁹ Currently, a double-blinded, randomized trial is under way in 182 centers in 21 countries to evaluate the benefit of perioperative beta blockage in patients undergoing noncardiac thoracic surgery. The study has entered 6400 patients and is set to accrue 10,000 patients.¹¹⁶

Late Perioperative Complications

Anastomotic Stricture

Although anastomotic stricture is never life-threatening, it is not uncommon and, if severe, negates the primary benefit of intestinal continuity after esophageal replacement. A large retrospective meta-analysis concluded that the incidence of symptomatic stricture is somewhat higher after anastomosis in the cervical position (28%) than after Ivor Lewis resection (16%).²³ This is in part because of the higher incidence of leak after cervical anastomosis. In an examination of risk factors of benign stricture after transhiatal esophagectomy, the use of a stapled anastomosis, an anastomotic leak, and the presence of cardiac disease were the only risk factors identified for the development of stricture.¹¹⁷ Earlier studies had identified intraoperative blood loss and poor vascularization of the gastric conduit as risk factors.^{118,119} From these studies, it is apparent that three factors influence the development of postoperative stricture: infection, ischemia, and mechanical issues.

Anastomotic leak is a well-known risk factor for the development of a delayed stricture. It is curious that Honkoop and associates¹¹⁷ found no difference in the incidence of delayed stricture between clinically overt leaks and those detected by swallow only. Preemptive bougienage dilation (7 to 10 days after operation) has been advocated by some physicians to prevent the development of stricture after cervical leak.¹²⁰ Ischemia is one of the major contributors to anastomotic leak, and it is difficult to determine what effect this alone has on the development of postoperative stricture. All efforts to avoid ischemia (adequate blood supply, systemic oxygen delivery, avoidance of congestion) should certainly be made to prevent both leak and stricture. It is also evident that mechanical factors influence the development of stricture. Law and colleagues⁹⁷ performed a randomized trial of hand-sewn versus EEA-stapled Ivor Lewis anastomosis. The incidence of stricture after the hand-sewn anastomosis was 9%, whereas that after stapled anastomosis was 40%. Strictures were not seen with the 33-mm EEA stapler but had a 12.5% incidence with the 29-mm stapler and a 43% incidence when a 25-mm stapler was

used. Not every esophagus will allow a 33-mm stapler, but it should be used whenever possible. Otherwise, a hand-sewn anastomosis or a different stapling technique should be considered. A retrospective study performed at the University of Texas MD Anderson Cancer Center indicated that side-to-side stapled esophagogastric anastomosis represented a trend in which this technique had lower associated postoperative dysphagia and need for stricture dilation compared with its hand-sewn counterparts.¹²¹

Postoperative stricture is usually managed by repeated bougie dilation. In Honkoop's study, three dilations, on average, were needed to achieve normal swallowing. Perforation occurred in 2 of 519 episodes of dilation. Both of these perforations resulted in death of the patient. In the study by Law and colleagues, 53% were treated by one dilation, 20% by two, 12% by three, and 8% by four. No patient in either study was treated by reoperation.

Martin and coworkers¹²² reported that most postesophagectomy patients will have some degree of dysphagia. Some have advocated early dilation of the anastomosis and conduit in patients with dysphagia even if there is no anatomic reason for the dysphagia.¹²³

Barthel and colleagues¹²⁴ advocate the use of a silicone stent as an alternative to serial dilations. They evaluated eight patients who had persistent anastomotic strictures after a transhiatal esophagectomy. They placed 13 stents in eight patients with strictures between 20 and 23 cm from the incisors. All strictures were less than 2 cm and had a predilation luminal diameter of 2 to 5 mm. The authors concluded that stent placement significantly prolonged the interval between endoscopic interventions that are necessary for management of strictures. However, their data did not show permanent resolution of the stricture after the stent was removed.

Postresection Reflux

Reflux of duodenal contents into the conduit occurs to some degree after esophagectomy in virtually all patients. It is not clear that preservation of the integrity of the pylorus protects against bile reflux. In fact, a study by Romagnoli and colleagues¹²⁵ involving 24-hour bile monitoring of the denervated gastric conduit in 16 patients showed elevated concentrations of bile in the stomach irrespective of the presence or absence of a drainage procedure.

The incidence of severe postoperative reflux requiring intervention after distal esophagectomy with esophagogastric anastomosis low in the chest approaches 20%.¹²⁶ For this reason, when esophageal replacement is contemplated for a distal peptic stricture, colon or jejunal interposition should be used. These conduits, in the isoperistaltic position, are more resistant to the effects of gastric reflux and provide active peristalsis that allows clearance of bile.

Impaired Conduit Emptying

Several factors have been implicated in delayed conduit emptying after esophagectomy; these factors include truncal vagotomy, absence of pyloric drainage procedure,

swelling at the pyloroplasty site, kinking of redundant conduit in the lower chest, and conduit that is too wide and patulous. Some of these variables are difficult to assess, whereas others have been carefully studied. After truncal vagotomy for ulcer disease, there is a 25% incidence of impaired gastric emptying.¹²⁷ Whether this applies to transposed stomach after esophagectomy is not clear. One study showed that delayed emptying after esophagectomy with gastric replacement was less in those undergoing pyloroplasty (the time of emptying of radio-labeled water was 378 minutes with no pyloroplasty versus 161 minutes in patients undergoing pyloroplasty).¹²⁸ Other studies showed no objective difference in gastric conduit emptying.¹²⁹ In any event, there is often poor correlation between gastric emptying tests and symptoms.

Fok and associates¹³⁰ conducted a prospective randomized trial of pyloroplasty versus no pyloroplasty in 200 patients undergoing Ivor Lewis esophagectomy with gastric reconstruction. There were no complications from the pyloroplasty procedure. Of the 100 patients who had no drainage procedure, 13 patients had symptoms of delayed gastric emptying. Two of these patients died as a result of aspiration pneumonia, one required reoperation, and three others had prolonged symptoms. The daily postoperative nasogastric drainage was not significantly different between the two groups. Gastric emptying measured at 6 months was 6 minutes in the pyloroplasty group and 24 minutes in the patients without pyloroplasty. The patients without pyloroplasty also had more symptoms attributable to impaired gastric emptying at 6 months than the pyloroplasty patients did. The authors strongly advocate a routine pyloric drainage procedure. The same group conducted a randomized trial of pyloroplasty compared with pyloromyotomy and found both to be effective and safe procedures.¹³¹ Six months after the procedure, gastric emptying was twice as fast in the pyloroplasty groups versus the pyloromyotomy group; however, the incidence of symptoms appeared to be no different.

Kim and associates¹³² reported on balloon dilation in 21 patients who had delayed gastric emptying after an esophagectomy. Gastric emptying before and after dilation was measured by radioisotope imaging. Single dilation was performed in 19 patients. Two patients required a second dilation. Gastric emptying improved after dilation in 67% of the patients; seven patients were greatly improved and six patients were slightly improved, whereas six patients showed no improvement. There were no complications. This is clearly a small case report, and larger studies need to be performed to observe any benefit from balloon dilation.

The width of the gastric conduit is also believed to influence the rate of emptying. The gastric tube should be kept narrow, with the width not significantly exceeding that of the antrum. A retrospective study examined the relationship between conduit emptying and size and found that patients with a narrow gastric tube had a far lower incidence of symptoms attributable to delayed gastric emptying (3%) than did patients with whole stomach (38%) or distal two-thirds stomach (14%) conduits.¹³³ A conduit that is too narrow, however, may become ischemic from a compromised arterial inflow and

venous congestion. In the authors' opinion, conduit diameter should not be less than 5 cm. Proper length of the gastric conduit is also important because excess conduit can fold over into the right chest and has been associated with impaired emptying.

Local Recurrence

Factors involved in local recurrence include resection margins and clearance of adjacent nodal disease. Tam and coworkers¹³⁴ found a correlation between the incidence of local recurrence and the lateral spread of tumor outside the esophageal wall (T3) but no correlation with tumor differentiation or lymph node metastasis. As discussed earlier, the importance of complete clearance of nodal tissue is debated among proponents of complete lymphadenectomy (by transthoracic or en bloc dissection) and proponents of simple transhiatal dissection.

The issue of recurrence with an incomplete linear margin is better understood. The palpable intraoperative *in situ* resection margin will be larger than the contracted gross postresection margin, which in turn is longer than the final fixed margin. Siu and colleagues¹³⁵ estimated that margins after removal of the esophagus were approximately 50% of the *in situ* margin. Descriptions of margin length must take this factor into account. Tam and coworkers¹³⁴ examined the *in situ* resection margins of 100 patients with squamous cell carcinoma of the esophagus. When the *in situ* margin was less than 5 cm, there was a 20% incidence of anastomotic recurrence; between 5 and 10 cm, there was an 8% chance; and when the margin was greater than 10 cm, there were no anastomotic recurrences. Wong¹⁶ further pointed out that it is difficult to obtain a 10-cm margin, because the length of the average esophageal tumor is 6 cm. Assuming the average esophagus is 25 cm in length, only distal esophageal tumors can, on average, be resected with a 10-cm margin if the larynx is to be conserved. Another author suggested that an adequate distal margin after resection of adenocarcinoma of the gastroesophageal junction should be 6 cm.¹³⁶

Long-Term (5-Year) Survival

Long-term survival remains an elusive goal for the medical and surgical oncologist caring for a patient with esophageal cancer. Despite advances in perioperative care that have reduced the perioperative mortality rate to 7% and less, 5-year survival has changed marginally during the past 2 decades. The 5-year survival described by Cunha-Melo and associates⁸⁶ in their analysis of cases reported between 1953 and 1978 (18%) is similar to that described in the meta-analysis by Hulscher and coworkers³¹ covering the years 1990 to 1999 (22%). It remains to be seen whether the introduction of neoadjuvant treatment for advanced esophageal cancers (invading through the esophageal wall or with positive nodes) will change the overall survival of patients with esophageal cancer. Three randomized trials using neoadjuvant chemoradiation before esophagectomy have been performed. A trial randomizing 100 esophageal cancer patients to preoperative chemoradiation followed by

transhiatal esophagectomy versus transhiatal esophagectomy alone showed that survival in the neoadjuvant group was 30% at 3 years versus 16% in the surgery-alone group; the difference was not statistically significant.¹³⁷ A European study randomizing 282 patients with squamous cell cancer to neoadjuvant chemoradiation followed by en bloc transthoracic esophagectomy and to esophagectomy alone found no difference in 5-year survival.¹³⁸ Walsh and coworkers¹³⁹ randomized 113 patients with adenocarcinoma to surgery alone versus chemoradiation followed by surgery. Five-year survival was approximately 50% in the neoadjuvant group and unusually poor in the surgery-alone group (8%); the difference was statistically significant. Larger trials have been attempted; however, they have encountered difficulty in enrolling patients in a randomized fashion, and the true benefit of neoadjuvant chemoradiation may never be measured.

A few isolated series in selected centers using radical en bloc dissection of the esophagus with three-field lymph node dissection have described 5-year survival rates in the 40% to 50% range.^{67,69} These results are discussed in the sections on en bloc resection and three-field lymph node dissection.

SUMMARY

The reduction in perioperative mortality of esophagectomy from more than 40% during the past 50 years to as low as 3% as described in several large academic centers is attributable to improvements in selection of patients, operative technique, and intensive care and early recognition and aggressive management of perioperative complications. Minimizing complications and optimizing chances of cure require that the skilled esophageal surgeon be familiar with the anatomy of the neck, chest, and abdomen and be well trained in and ready to use a variety of routes of esophageal resection and methods of reconstruction. As MIE has become more prominent, numerous institutions have reported their experience, suggesting an advantage to MIE over open surgery. However, randomized controlled trials need to be performed to affirm these claims.

SUMMARY

OVERVIEW: PRINCIPLES OF MULTIMODALITY THERAPY

Achieving real improvement in the treatment outcomes for esophageal cancer has been a slow process. Arguably, the major hurdles impeding our ability to diagnose and treat the disease were, for the most part, overcome in the last century. Establishing reliable and safe anesthetic techniques for thoracic surgery and minimizing mortality from an esophageal resection while maximizing local/regional control (to the extent that radical surgery is capable) had significant impact in placing surgery at the forefront of esophageal cancer therapy. Yet, the breakthrough discovery that would allow us to cure a significant percentage of people with this diagnosis eludes us. Radical surgery reached a ceiling of effectiveness, and the field is now in the process of backing away from larger resections in favor of minimizing trauma and operative morbidity. Nominal improvements in survival outcomes have been made by avoiding mortality rather than salvaging sicker patients, by focusing on more appropriate patient selection by avoiding those that are at high risk for perioperative mortality or distant failure. Whereas this gives the impression that we are improving, it leaves behind the patients who are not salvageable with existing local/regional therapies. Even though resection has been considered the backbone of esophageal cancer treatment, we have learned that radical resections with or without other forms of local/regional therapy are not adequate to cure advanced disease in most cases. Distant recurrence

continues to be the main cause of death in patients with esophageal cancer.

As long as we lack truly effective methods of screening, most patients with esophageal cancer will present with locally advanced disease. Strategies that address both local/regional as well as distant disease have the most potential to realize real gains in survival outcomes for patients who have esophageal cancer. The early evolution of a multimodality treatment paradigm started decades ago, first with the recognition that a cure could be obtained in some patients without the use of surgery. But the relatively poor local/regional control attained with (nonoperative) medical therapy led to the concept that multimodality therapy that involved surgery could be feasible and could more effectively address both compartments of disease, local and lymphatic. The combination of local and systemic therapies has become the focus of many clinical trials investigating the role and timing of each method.

Preoperative (neoadjuvant) combination therapy is based on principles of patient tolerance and compliance with therapy compared to postoperative therapy (adjuvant). What became apparent in early trials of multimodality therapy was that patients were more frequently able to receive all of their therapy if it was administered before surgery. Also of interest is that when patients receive therapy while tumor is *in vivo*, therapy response can be directly observed via imaging and later pathologically assessed after resection. These clinical findings amount to surrogate endpoints of efficacy. In contrast, advocates of adjuvant therapy administer therapy only to

patients with indications based on final pathologic analysis, thus sparing some patients the unnecessary toxic effects of treatment.

RADIATION THERAPY

Before the surgical era, radiation was considered the primary treatment modality for esophageal cancer. Early experience with radium bougies demonstrated esophageal tumor regression but rarely complete cure. With the evolution of surgical care, external beam radiation became a component of a multidisciplinary approach to esophageal cancer therapy with the goal of sterilizing areas within or around the operative field.¹

Preoperative Radiation Therapy and Surgery

Randomized trials of preoperative radiation therapy for esophageal cancer focused on administering intermediate radiation doses of 20 to 40 Gy for the purpose of decreasing local recurrences (Table 39-1). The lower dose of radiation was given in an attempt to avoid surgical/treatment toxicity. These trials included primarily patients with squamous cell carcinoma (SCC), and none of the trials demonstrated significant benefits of adding radiation therapy to resection.²⁻⁵ A meta-analysis of 1147 patients by Arnott et al (1998) reiterated that preoperative radiation alone does not improve survival in resectable esophageal cancer.⁶ However, lumping patients with different tumor histology and location into one group for the analysis may have confounded the results. Another potential criticism of these studies is that modern forms of radiation therapy are more precise, effective, and less toxic, allowing for higher dose administration to achieve a desired effect.

Surgery and Adjuvant Radiation Therapy

The patients that surgeons were faced with decades ago were different than patients we commonly see today. Squamous cell cancer, with its inherent comorbidities, was the dominant histology. Tumors were large, often involving surrounding structures, and patients were often sick with malnutrition, cirrhosis, and/or lung disease. Preoperative staging was limited to barium swallow and very low resolution computed tomography imaging, yielding

very inaccurate results. Attaining complete surgical margins (R0) was frequently difficult, and failure within or around the surgical field was common. The issue of local/regional recurrences following resection led to the consideration of postoperative radiation therapy (PORT) for esophageal cancer. The rationale for this approach was the ability to deliver a higher dose (40 to 60 Gy) of radiation postoperatively without worsening perioperative complications. Although PORT was described in the 1960s, it was in the 1980s that some prospective trials demonstrated that PORT could achieve better local control and perhaps improve survival compared with surgery alone. In fact, PORT for esophageal cancer appeared to be potentially beneficial in some of the phase III trials (Table 39-2).⁷⁻¹⁰ However, the results from the four published randomized trials are conflicting: some were positive, whereas others showed no benefit. Those that showed a benefit have been criticized for selection bias. Notably, none of these trials used newer radiation techniques such as intensity-modulated radiation therapy and proton therapy, which have become more widely available than they were at the time of these studies.

CHEMOTHERAPY

There are several reasons that chemotherapy would seem to be an attractive treatment modality for esophageal cancer. The most frequent mode of death from esophageal cancer is attributed to metastatic disease. Naturally, the concept of delivering systemic chemotherapy to treat hematogenous disease would seem advantageous. Chemotherapy is also capable of downstaging larger, marginally resectable tumors, which could allow for an improvement in complete (R0) resection rates and decrease the incidence of local/regional recurrence.¹¹ Shrinking tumors also allows patients to become nutritionally replete and independent from supplements as dysphagia resolves. Finally, chemotherapy acts synergistically with radiation as a local/regional therapy, further strengthening arguments for its use.

Current chemotherapeutic regimens are typically delivered as a doublet or triplet combination based on platinum compounds given in concert with 5-fluorouracil (5-FU) or a taxane.¹² This approach has had encouraging results in early phase II trials, in some cases producing clinical responses in up to 50% of patients with the occasional complete pathologic response.

Preoperative Chemotherapy and Surgery

There are several prospective randomized trials comparing chemotherapy followed by surgery with surgery alone (Table 39-3).¹³⁻²² A landmark trial by Roth and colleagues compared esophagectomy against cisplatin-based chemotherapy followed by esophagectomy in patients with mid-distal esophageal SCC.¹³ The major contribution of this study was the observation that patients who achieved a major or complete response to chemotherapy (47% and 5%, respectively) reached a significantly longer median survival compared with nonresponders (20 months versus 6 months; $P = 0.008$). This study demonstrated that within populations of similar tumors there is biological

heterogeneity leading to variable susceptibility to therapy, and treatment response translated to survival outcome benefits.

One of the largest randomized trials of combined preoperative and postoperative chemotherapy versus surgery alone in esophageal cancer patients was the North American Intergroup trial (INT 0113).^{17,18} The addition of chemotherapy to surgery in this trial failed to demonstrate a significant survival advantage. One of the notable drawbacks of the trial included a low compliance with therapy in both the preoperative (66%) and postoperative (38%) chemotherapy regimens, and outdated staging and response evaluation based on the use of barium swallow. The observed local/regional recurrence rate in this trial

was 30%. These results became one of the motivating influences to perform more radical surgery and perhaps to include radiation therapy to the multimodality treatment regimen in future trials. Ultimately, the 3-year survival rate in this trial did not reach its goals (23% for chemotherapy plus surgery versus 26% for surgery alone; $P = 0.74$).

In contrast to the Intergroup 0113 trial, the Medical Research Counsel (MRC) trial, a large prospective, randomized trial that also evaluated the benefit of chemotherapy plus surgery versus surgery alone in locally advanced esophageal cancer, demonstrated significant survival improvement with additional therapy.¹⁹ This trial included 802 patients randomized to receive chemotherapy followed by esophagectomy versus esophagectomy alone. The chemotherapy that was administered in this trial (cisplatin + 5-FU) was tolerated far better than the treatment in the Intergroup trial, with the MRC trial showing an 86% compliance rate with therapy. The additional treatment resulted in a survival benefit compared to surgery alone. This advantage persisted after a median follow-up duration of 6 years when the long-term results of the trial were published in 2009; the 5-year survival rates of patients treated with chemotherapy plus surgery were 23% compared to 17% with surgery alone ($P = 0.03$). Patients with either adenocarcinoma or SCC experienced a survival benefit.²⁰

The 2006 MRC Adjuvant Gastric Infusion Chemotherapy (MAGIC) trial also demonstrated a survival advantage using preoperative chemotherapy.²¹ In this randomized trial, patients received perioperative treatment with cisplatin, 5-FU, and epirubicin in three cycles before and after surgery. Patients in the treatment arm had better overall (hazard ratio [HR], 0.75 [95% confidence interval (CI), 0.60-0.93]; $P = 0.009$) and progression-free (HR, 0.66 [95% CI, 0.53-0.80]; $P < 0.001$) survival compared to those in the surgery-alone arm. Note that most enrolled patients in this trial had gastric carcinoma, with only a subgroup having esophageal or gastroesophageal junction (GEJ) tumors.

Overall, trials of preoperative chemotherapy have reported a mixture of efficacy. The MRC and MAGIC trials indicate that the addition of chemotherapy to esophagectomy for resectable esophageal cancer is beneficial. However, completeness of resection in these trials is also clinically relevant. The Intergroup trial had a very

low R0 resection rate (partially because of poor compliance with surgery). Considering that R0 resection is a significant predictor of survival in most patients with solid organ malignancies, the question arises whether chemotherapy combined with radical en bloc surgery or chemoradiotherapy and surgery would achieve better R0 resection rates and better overall outcomes.

Surgery and Adjuvant Chemotherapy

Achieving accurate clinical staging of esophageal cancer is a challenge that frequently results in the under- or overstaging of patients.²³ A more accurate method of determining the disease stage is the assessment of a surgical specimen in a previously untreated patient.²⁴ Clinicians who advocate for adjuvant chemotherapy favor its use because theoretically, one could spare the inappropriate use of additional therapy in clinically overstaged patients by examining the surgical specimen. This tactic reserves therapy only for patients who have pathologic stage characteristics associated with a high recurrence rate (e.g., lymph node involvement).

Summarizing the available data (Table 39-4), there are no phase III data supporting adjuvant chemotherapy alone for patients with esophageal adenocarcinoma.²⁵⁻²⁸ This is a bit distressing for clinicians who prefer to resect prior to any therapy. If the resection was complete and radical, those patients who show nodal involvement on pathologic analysis are faced with a high risk of distant failure, but the only trial with data supporting postoperative therapy used chemotherapy *and* radiation.²⁹ Regarding SCC histology, the results were mixed, with some trials showing benefit and others none. Those that have shown benefit have been criticized for selection bias and early study termination. Nonetheless, chemotherapy is often offered to SCC patients with nodal involvement on pathology.

CHEMORADIATION

Definitive Combined Chemoradiation

Both chemotherapy and radiation have demonstrated cytotoxic effects on esophageal cancer when given as individual therapy. When these two therapies are

administered concurrently, there is a synergistic effect, with increased tumor cytotoxicity at lower doses. The rationale for using chemoradiation for GEJ and thoracic esophageal cancers was based on results of definitive chemoradiation for cervical esophageal squamous tumors. This was later translated to use in the thoracic esophagus. Table 39-5 summarizes the initial studies on definitive chemoradiation for the thoracic esophagus that have helped to shape current therapeutic algorithms.

Radiation Therapy Oncology Group (RTOG) 85-01 is the landmark definitive concurrent chemoradiation trial on thoracic esophageal cancer.²⁸ This was a nonoperative randomized prospective multi-institutional trial comparing chemoradiation with radiation alone in 121 patients with esophageal SCC or adenocarcinoma (T1-3N0-1M0). Sixty-one patients received cisplatin and 5-FU with a radiation dose of 50.4 Gy, and 60 patients received a radiation dose of 64.8 Gy alone (see Table 39-5). At a median follow-up duration of 17.9 months, both survival and local/regional recurrence rates favored chemoradiation over radiation alone. The 2-year survival rate was 38% in the chemoradiation group versus 10% in the radiation therapy-only group ($P < 0.001$). The study terminated prematurely when early analysis revealed that statistical stopping points as a result of treatment superiority were reached. Grade 4 toxicity was much higher in the chemoradiation group (20% versus 3%), but the authors accepted the toxicity of chemoradiation as a tradeoff for improved overall survival.

In the long-term follow-up for the RTOG 85-01 trial, coupled with the addition of 73 nonrandomized patients who received chemoradiation, survival advantages persisted in the treatment arm.³⁰ At a minimum follow-up duration of 5 years, none of the patients in the radiation therapy-only group was alive, whereas 26% of the randomized and 14% of the nonrandomized patients who received definitive chemoradiation were alive ($P < 0.001$). Moreover, 22% of the patients in the randomized group survived for at least 8 years. Survival in patients with SCC was better than that of patients with adenocarcinoma (21% versus 13%), although not significantly. Some patients died as a direct result of chemoradiation toxicity (2%). However, the toxic effects in patients in the

chemoradiation group who survived for more than 90 days did not differ from those in the patients in the radiation therapy-only group. This was the first randomized study to establish that both esophageal SCC and adenocarcinoma could be cured in some patients without performing resection.

A major issue with definitive chemoradiation is very high rates of local/regional therapy failure, reported in up to 60% of patients in trials omitting surgery. Improving nonoperative control of the primary disease site became the focus of subsequent esophageal cancer trials. The Intergroup 0123/RTOG 94-05 trial modified the intensity of radiation therapy given concurrently with chemotherapy in an attempt to improve local/regional disease control.³¹ The investigators randomized 218 eligible patients with esophageal SCC ($N = 187$) or adenocarcinoma ($N = 31$) having T1-4N0-1M0 disease. Half of the patients (109) received induction chemotherapy followed by concurrent chemoradiation with a higher radiation dose (64.8 Gy); the other half was treated with the same chemotherapy but with a radiation dose of 50.4 Gy. The compliance rate for this aggressive regimen was 69% in the induction phase but only 48% in the chemoradiation phase. The radiologic complete response rate was 47%. At a median follow-up duration of 16 months, the survival and local/regional disease control rates did not differ significantly from those in the RTOG 85-01 trial. Importantly, the toxicity in RTOG 94-05 was worse, with excess treatment-related deaths occurring in the high-dose radiation therapy group. Notwithstanding the nuances of radiation therapy administration, for which the Intergroup 0123/RTOG 94-05 trial has received criticism, the study established the currently used radiation dose of 50.4 Gy.³¹

Selective Surgery

Randomized trials comparing chemoradiation with or without surgery have illustrated that cure is possible without surgical resection. We know that after chemoradiation, patients belong to one of three groups: those who are already cured by the chemoradiation therapy, those who would currently be considered incurable because of

systemic disease (ultimately leading to distant failure), and those who require further local/regional therapy (resection) to effect a cure. Selecting patients who would benefit from surgery after chemoradiation and identifying those who would not benefit compels the possibility of reserving surgical resection for those who are appropriate risks and require resection for cure. Incomplete responders would go for surgery, and patients who are complete responders or who will progress to distant disease would avoid resection. The problem is knowing to which group an individual patient belongs.

Two randomized trials have sought to evaluate a selective surgical approach as an adjunct to definitive medical therapy in patients with squamous histology.^{32,33} Both show high clinical response rates to therapy, suggesting that a selective surgical approach using chemoradiotherapy represents an equivalent outcome to using surgery for every patient who receives chemoradiation therapy. Similarly, a phase II study including patients with adenocarcinoma was completed by the RTOG (protocol 0246) showing feasibility of this approach in a multi-institutional study albeit with high medical mortality (5/41).³⁴ None of these studies was designed to show superiority over a planned trimodality chemoradiotherapy + surgery approach and therefore conclusions cannot be reached on that question. What the RTOG 0246 study did show is that among the patients taken selectively to resection, 17 of 18 patients had disease in the pathologic specimen. The only patient in the study that was resected to a pathologic complete response had insisted on surgical therapy. These results underscore the positive predictive value of surgeons who are experienced in multimodality therapy to predict when viable tumor will be present in the specimen. Several patients in that series

also presented for later salvage resection, indicating that accuracy is incomplete. It seems that it is easier to derive when a patient has had an incomplete response than to accurately recognize a complete response.

Preoperative Chemoradiation and Surgery

The paradigm of chemoradiation followed by resection is the current treatment of choice because this maximizes local/regional control with the potential to treat early invisible metastatic disease. But the effect on systemic disease should not be overstated. This treatment is really focused on local/regional control, and the record of curing distant disease with this regimen is not optimal.

Over a 2-decade period from 1992 to 2012, there have been nine randomized trials of trimodality treatment for esophageal cancer. Table 39-6 reviews the doses of radiation and types of chemotherapy used in these trials.³⁵⁻⁴³ The mixture of histology, mainly SCC and adenocarcinoma, varied significantly between trials. Many of the trials were underpowered and failed to reach the accrual goals or statistical endpoints. Only three of the nine trials favored therapy over surgery alone. Two of the positive trials, Walsh et al (1996)³⁸ and the Cancer and Leukemia Group B 9781 study by Tepper et al,⁴² were heavily criticized. The Walsh trial had statistical errors and unusually poor surgical outcomes in the surgery arm. The Tepper trial accrued a tenth of their patient goal.

The most recent randomized trial comparing chemoradiation followed by surgery with surgery alone for esophageal and GEJ cancer was the ChemoRadiotherapy for Oesophageal cancer followed by Surgery Study (CROSS) reported by van Hagen et al (2012).⁴³ The trial

reported on 368 patients with surgically resectable (T1N1-T2,3N0,1) disease. Of the 366 patients included in their analysis, 188 underwent surgery alone, whereas 178 underwent chemoradiation followed by surgery. Seventy-five percent of the patients had adenocarcinoma, whereas 23% had SCC. The chemotherapy regimen consisted of carboplatin and paclitaxel given for 5 weeks with concurrent three-dimensional conformal radiation therapy at a dose of 41.4 Gy given in 23 fractions 5 days a week. Physicians performed resection within 4 to 6 weeks in the treatment group and immediately after randomization in the control group. The toxicity of chemoradiation was relatively low, and the toxic effects included leukopenia (6%), neutropenia (2%), anorexia (5%), and fatigue (3%). The R0 resection rate was much higher in the trimodality group (92%) than in the surgery-alone group (69%; $P < 0.001$). Complete pathologic response (ypT0N0M0) was significantly more prevalent in the SCC patients (49%) than in the adenocarcinoma patients (29%). After similar surgical node harvest in both groups, pathologic analysis revealed N1 disease in 75% of the patients in the surgery-alone group and 31% of those in the chemoradiation plus surgery group ($P < 0.001$). At a median follow-up of 45 months, patients receiving trimodality therapy had a significantly longer median overall survival (49.4 months) compared to patients undergoing surgery alone (24 months; HR, 0.65 [95% CI, 0.49-0.87]; $P = 0.003$). The estimated 5-year survival rate in the trimodality therapy group was 47%, compared to 34% in the surgery-alone group (HR, 0.65 [95% CI, 0.49-0.87]; $P = 0.003$). Likewise, the median disease-free survival duration was better in the trimodality group (duration not reached in the trimodality therapy group versus 24.2 months in the surgery-alone group; HR, 0.49 [95% CI, 0.35-0.69]). Subgroup analysis according to histology demonstrated that the trimodality approach was beneficial in both SCC ($P = 0.01$) and adenocarcinoma ($P = 0.049$) patients, although the benefit was clearly more pronounced in SCC patients. Interestingly, in a hazard ratio analysis, trimodality therapy favored males, SCC, and clinically node-negative disease (HR, 0.42 [95% CI, 0.23-0.74]; $P = 0.003$) but not those with node-positive disease (HR, 0.80 [95% CI, 0.57-1.13]; $P = 0.21$).⁴³

The Role of Surgery in Trimodality Therapy for Esophageal Cancer

Preoperative chemoradiation improves R0 resection and local/regional recurrence rates and results in pathologic complete responses in some patients, but other subgroups of esophageal cancer patients clearly derive no benefit from neoadjuvant therapy over surgery alone. Likewise, patients whose cancer is cured by chemoradiation may not derive additional benefits from surgery. The problem is, we are currently unable to accurately select those groups of patients and thus must search for surrogate markers predictive of treatment outcome. A simple, reproducible, validated molecular marker has yet to be identified for clinical decision making regarding therapy. Pathologic specimen analysis for evaluation of tumor histoviability after preoperative therapy has emerged as a predictor of survival in esophageal cancer patients.⁴⁴ Histoviability is a

short-term surrogate endpoint for survival. Above and beyond the potential for surgical cure, pathologic specimens provide answers necessary for the development of novel treatment strategies.

With respect to survival, how much does esophageal resection contribute to overall and disease-free survival over definitive chemoradiotherapy? This question has been the focus of two European trials. In the Fédération Francophone de Cancérologie Digestive (FFCD) 9102 trial, the researchers randomized 259 patients with operable T3N0-1M0 esophageal cancer (88% with SCC) that responded to initial chemoradiation to undergo more chemoradiation followed by observation or resection (nonresponders received off-protocol treatment).³² The 2-year survival rate was 34% in the chemoradiation-only arm versus 40% in the chemoradiation plus surgery arm ($P = 0.44$), with median survival durations of 17.7 months and 19.3 months, respectively. The trend in local control rates favored surgery, but not significantly (57% for chemoradiation only versus 66% for chemoradiation plus surgery). Most notably, the investigators observed an initial toxicity cost in terms of a higher mortality rate in the chemoradiation plus surgery group, which likely negated any benefit that may have been derived from the surgery. The 90-day mortality rate was 9.3% in the chemoradiation plus surgery group and only 0.8% in the chemoradiation group.

A German trial reported by Stahl et al (2005) was a multi-institutional phase III trial with 172 patients who received preoperative induction chemotherapy followed by concurrent chemoradiation.³³ All patients received chemotherapy plus chemoradiation therapy but were randomized to observation or surgery. They limited the study to patients with locally advanced (T3-4N0-1M0) upper to middle esophageal SCC, but in contrast with the FFCD 9102 trial, they included both responders and nonresponders. At a median follow-up duration of 6 years (range, 1.4 to 9.3 years), the authors reported that local/regional control was markedly better with surgery than with observation, but this failed to translate into a statistically significant survival advantage. Similarly to the French trial, they concluded that even though patients in the surgery arm were less likely to die of their cancer, they had a much higher risk of treatment-related deaths than did the patients in the nonsurgical arm. Specifically, the mortality rate was 12.8% in the surgery arm versus 3.5% in the nonsurgical arm. Both this trial and the French study consisted predominantly of SCC patients who consistently had better responses to concurrent chemoradiation than did adenocarcinoma patients. Both trials are criticized for excess mortality in surgical patients.

Murphy and colleagues set out to answer the question about the additional role of surgery after chemoradiation in a retrospective review of 143 patients with clinical stage III esophageal adenocarcinoma eligible for trimodality therapy.⁴⁵ They included only the patients deemed to be appropriate candidates for surgery after completion of preoperative chemoradiation; 114 patients underwent resection, whereas 29 did not because they refused surgery or their physicians chose observation over resection. The demographics of the groups who did and did not undergo resection were similar. Survival analysis

demonstrated that the patients who underwent surgery had overall and disease-specific mortality rates of 50% and 54%, respectively. Multivariable analysis identified only poor tumor differentiation (HR, 2.04 [95% CI, 1.23–3.37]) and resection (HR, 0.504 [95% CI, 0.28–0.89]) to be independently associated with overall survival. This study suggests that resection is an integral component of trimodality therapy for locally advanced esophageal adenocarcinoma.⁴⁵

Chemoradiation with Surgery versus Chemotherapy with Surgery

Currently, chemotherapy is truncated when given concomitantly with radiation therapy. Therefore, its effect is sensitizing rather than systemic; treatment is focused on the area of radiation. If true systemic doses of chemotherapy were added to the treatment, would this improve the outcomes in esophageal cancer patients? Two randomized trials compared chemotherapy versus chemoradiation followed by surgery.^{46,47} Stahl and coworkers (2009)⁴⁶ addressed this question in a phase III study in which they randomized patients with resectable but locally advanced type I–III GEJ adenocarcinoma to undergo either 15 weeks of chemotherapy followed by surgery or 12 weeks of chemotherapy followed by 3 weeks of concurrent chemoradiation (30 Gy) and subsequent surgery. At a median follow-up duration of 45 months, they demonstrated both a 3-year survival and local control advantage with chemoradiation plus surgery. These advantages were not statistically significant, however ($P = 0.07$ and $P = 0.06$, respectively), likely because of a type II error, given the accrual of only 126 patients in the trial. Notably, the hospital mortality rate differed markedly in the two groups: 3.8% for the chemotherapy plus surgery group and 10.2% for the chemoradiation plus surgery group ($P = 0.26$). A randomized phase II trial by Burmeister and colleagues⁴⁷ also failed to show a benefit to chemoradiation therapy over chemotherapy followed by surgery, but they noted that the R0 resection rate was higher when radiation was added to the therapy, especially in bulky tumors. One should note that the comparison in the Stahl et al trial really involved induction therapy (albeit shorter), which is not the standard for concurrent chemoradiation.

Postoperative Chemoradiation

Investigators have demonstrated the feasibility of postoperative chemoradiation in multiple trials, the largest of which was reported by MacDonald et al (2001).²⁹ This study mainly included gastric cancer patients but also included cardia cancer patients. It demonstrated better survival with surgery and adjuvant chemoradiation than with surgery alone. The main limitation of this adjuvant approach is the administration of chemoradiation in patients who are already somewhat weakened from surgery. Also, irradiation of tissue conduits used to reconstruct intestinal continuity may have short- and long-term side effects. There has never been a trial evaluating the benefit of adjuvant therapy after radical surgery (en bloc and D2 lymphadenectomy).

META-ANALYSIS

A meta-analysis by Sjöquist et al⁴⁸ of 24 trials and 4188 patients focusing on survival after neoadjuvant chemotherapy or chemoradiotherapy for resectable esophageal carcinoma provided evidence for survival benefit of multimodality therapy versus surgery alone. The clear benefit of neoadjuvant chemoradiation over chemotherapy was not demonstrated, however.

SUMMARY

Multimodality therapy for esophageal cancer will continue to evolve. Very soon, molecular predictors will shed light on which patients to treat with surgery versus those who will benefit entirely from chemoradiation alone. Clearly the tumor biology/susceptibility is present; it is only a matter of identifying the appropriate patients to focus on. Targeted therapies for this cancer are limited to trastuzumab, but only 10% to 15% of advanced patients are eligible for this therapy at this time. Our hope is to evolve that type of treatment into potentially curable patients as well. Finally, the accuracy of pretreatment disease staging is not fully addressed in this chapter but is known to be suboptimal. Too much heterogeneity exists within the spectrum of cTNM, mostly because imaging techniques are just not sensitive enough to deliver the necessary information with accurate results. This will become even more important as alternative treatment strategies emerge.

MEDIASTINAL ANATOMY

The anatomic boundaries of the mediastinum include the thoracic inlet superiorly, the diaphragm inferiorly, the sternum anteriorly, the spine posteriorly, and the pleural spaces bilaterally. It is convenient to divide the mediastinum into anatomic compartments that provide a method for classification of disease processes.

A classic description divides the mediastinum into four compartments: superior, anterior, middle, and posterior (Fig. 40-1). The superior mediastinum includes all structures from the thoracic inlet superiorly to an imaginary plane that includes the lower edge of the manubrium and the lower edge of the fourth thoracic vertebra. The inferior mediastinum, which lies below this boundary, is further divided into the anterior, middle, and posterior compartments. The boundary between the anterior and middle compartments is the anterior pericardium, whereas the border between the middle and posterior compartments is the posterior aspect of the tracheal bifurcation, pulmonary vessels, and pericardium. In this four-compartment model, the upper portions of the trachea and esophagus are contained within the superior mediastinum; the lower portions are contained within the middle and posterior mediastinum.

Shields proposed a simpler three-compartment model consisting of an anterior compartment, a middle (or

visceral) compartment, and a posterior compartment (paravertebral sulcus; Fig. 40-2).¹ All three compartments are bounded inferiorly by the diaphragm, laterally by the pleural space, and superiorly by the thoracic inlet. The anterior compartment is contained anteriorly by the sternum and posteriorly by the great vessels and pericardium and this compartment contains the thymus, internal mammary vessels, areolar and adipose tissue, and potentially pathologic structures such as ectopic parathyroid tissue or a retrosternal goiter. The middle mediastinum is bordered posteriorly by the ventral surface of the thoracic spine; it occupies the entire thoracic inlet and contains the majority of mediastinal structures, namely, the great vessels, heart, pericardium, trachea, proximal mainstem bronchi, vagus nerves, phrenic nerves, esophagus, thoracic duct, descending aorta, and azygos venous system. The posterior compartment (paravertebral sulcus or sulci) consists of potential spaces along the thoracic vertebrae that contain the sympathetic chain, proximal portions of the intercostal neurovascular bundles, thoracic spinal ganglia, and distal azygos vein. Whereas some anatomists may argue that the paravertebral sulci are not truly a mediastinal space, they often harbor disease processes that are classically considered in the posterior mediastinum (i.e. neurogenic tumors). Detailed sagittal views of mediastinal anatomy are depicted in Figures 40-3 and 40-4.

FIGURE 40-1 ■ Four-compartment model of the mediastinum.

FIGURE 40-2 ■ Three-compartment model of the mediastinum.

POTENTIAL SPACES IN THE MEDIASTINUM

For ease and accuracy of communication in describing pathologic abnormalities (most commonly lymph node enlargement), several potential mediastinal spaces are described. The pretracheal space is a triangular space bounded anterolaterally by the superior vena cava and right brachiocephalic vein on the right, the aorta and pericardium on the left, and the trachea posteriorly. Continuing inferiorly from the pretracheal space is the subcarinal space. This location is bounded superiorly by the carina, laterally by the two main-stem bronchi, anteriorly by the back of the right pulmonary artery, and posteriorly

FIGURE 40-3 ■ Right mediastinal view. *LBCV*, Left brachiocephalic vein; *RBCV*, right brachiocephalic vein; *RMB*, right main bronchus; *RPA*, right pulmonary artery; *SVC*, superior vena cava.

FIGURE 40-4 ■ Left mediastinal view. *IMV*, Internal mammary vessels; *LA*, left atrium; *LBCV*, left brachiocephalic vein; *LMB*, left main bronchus; *LSCA*, left subclavian artery; *LV*, left ventricle.

by the esophagus (see Fig. 40-3). The pretracheal and subcarinal spaces are routinely explored in mediastinoscopy and endobronchial ultrasound. The aortopulmonary window is the space bounded superiorly by the aortic arch, medially by the trachea and esophagus, inferiorly by the pulmonary artery, and laterally by the pleura. This space contains lymph nodes, the ligamentum arteriosum, and the left recurrent laryngeal nerve (see Fig. 40-4). Routine cervical mediastinoscopy does not fully access this space, but anterior mediastinotomy (Chamberlain procedure), extended cervical mediastinoscopy, and thoracoscopy or thoracotomy can all provide access to the aortopulmonary window.

MEDIASTINAL LYMPH NODE ANATOMY

The adoption of a common thoracic regional lymph node classification by the American Joint Committee on Cancer and the Union for International Cancer Control in 1997,

FIGURE 40-5 ■ Regional lymph node stations for lung cancer staging. Ao, Aorta; A-P, aortopulmonary; PA, pulmonary artery. (From Mountain CF, Dresler CM: Regional lymph node classification for lung cancer staging. *Chest* 111:1718–1723, 1997.)

known as the Mountain-Dresler chart, has found widespread acceptance (Fig. 40-5).² This system classifies lymph nodes into 14 stations, of which stations 1 through 9 are contained within the mediastinal pleura and are considered to be mediastinal lymph nodes. The highest mediastinal station (level 1), upper right and left paratracheal nodes (level 2R, 2L), lower right and left paratracheal nodes (level 4R, 4L), and the subcarinal nodes (level 7; see Fig. 40-3) are the only mediastinal nodal stations accessible by standard cervical mediastinoscopy, while stations 5 (subaortic nodes) and 6 (para-aortic nodes; see Fig. 40-4) require an alternative approach such as extended mediastinoscopy or anterior mediastinotomy (Chamberlain procedure) or, rarely, endoscopic ultrasound (EUS).

INDICATIONS FOR MEDIASTINAL LYMPH NODE ASSESSMENT

The most common indication for surgical assessment of mediastinal lymph nodes is non-small cell lung cancer (NSCLC). Other indications include mediastinal lymphadenopathy of unknown etiology, mediastinal masses, primary tracheal tumors, and occasional esophageal tumors. Rare indications for mediastinoscopy include drainage of bronchogenic cysts, abscess drainage, identification of ectopic parathyroid tissue, and tissue sampling for causes of superior vena cava syndrome.

EFFICACY AND UTILITY OF MEDIASTINOSCOPY

Ideally, levels 2R, 2L, 4R, 4L, and 7 should be sampled (with at least one specimen from each level) during mediastinoscopy, though this ideal is seldom achieved. It is estimated that approximately half of false-negative mediastinoscopy results were due to pathologically positive mediastinal nodes not accessible by the mediastinoscope.³ A retrospective series comparing conventional mediastinoscopy to video-assisted mediastinoscopy has demonstrated a significantly lower complication rate (3.6 versus 1.6; $P = 0.03$), higher number of sampled lymph nodes, and lower number of missed positive lymph nodes after definitive lung resection with the use of video mediastinoscopy at the time of staging.⁴ Another retrospective series also showed a higher average number of lymph node samples (7 versus 5; $P < 0.001$) and number of lymph node stations sampled (3.6 versus 2.6; $P < 0.01$) with video mediastinoscopy, but in contrast to the previous study, there was a higher complication rate with video assistance (3.8% with versus 0.8% without; $P = 0.04$), which was attributed to a more aggressive dissection.⁵ The most frequent nodal station to be implicated in a false-negative result at time of eventual pulmonary resection was level 7 (approximately 70% of surprise N2 cases found at thoracotomy).⁵ However, almost 90% of these false-negative cases at level 7 were in the conventional mediastinoscopy group, only one false-negative level 7 case resulted after video mediastinoscopy.⁵

The use of modern imaging techniques, including high-resolution computed tomography (CT) and positron emission tomography (PET), has led to an appropriately selective strategy for invasive mediastinal lymph node assessment, especially for patients with stage I NSCLC. Some series have shown that the sensitivity and negative predictive value of positron emission tomography–computed tomography (PET/CT) approaches levels achieved with cervical mediastinoscopy (Table 40-1).^{6,7} However, reviews of large series have reminded surgeons to interpret PET results with caution. In one such study in which preoperative PET (alone) was followed by mediastinoscopy, the sensitivity of PET was 64.4%, specificity was 77.1%, positive predictive value was 44.6%, negative predictive value was 88.3%, and accuracy was 74.3%.⁸ In a similarly sized series that evaluated

combined PET-CT in patients who subsequently underwent mediastinoscopy, these values improved with a sensitivity of 70%, specificity of 94%, positive predictive value of 64%, and negative predictive value of 95%.⁹ However, both studies demonstrate a clinically important number of false-positive results with PET or PET/CT that, if accepted without confirmation, would result in unnecessary induction therapy or, in some practices, the possibility of the patient not being offered surgical management at all. These results suggest the continued need for pathologic confirmation of mediastinal lymph node staging before definitive management.

The European Society of Cardiothoracic Surgery has provided recommendations for mediastinal lymph node assessment in preoperative staging of NSCLC (Fig. 40-6).⁷ Similarly, the National Comprehensive Cancer Network guidelines currently recommend preoperative PET/CT scanning and pathologic mediastinal lymph node evaluation (either mediastinoscopy or endobronchial ultrasound-transbronchial needle aspiration [EBUS-TBNA]), EUS, or CT-guided biopsy for clinical stage IA–IIIB NSCLC disease.¹⁰ However, a cost-effectiveness analysis found that patients with clinical stage I lung cancer staged by PET/CT benefit little from mediastinoscopy.¹¹ In this series of stage I NSCLC patients who underwent mediastinoscopy, only 3% demonstrated N2 disease, with an additional 3.6% found to have occult N2 disease after their definitive surgery.¹¹ With this rate of N2 disease, mediastinoscopy added 0.008 years of life expectancy, costing more than \$250,000 per life-year gained.¹¹ Many practitioners do not routinely perform mediastinoscopy for patients with clinical stage IA or IB disease after CT and PET screening. Exceptions may include patients with central tumors, bronchoalveolar cell carcinoma, or in situations in which the primary tumor has low fluorodeoxyglucose uptake and there are enlarged, but PET-negative, mediastinal nodes.⁷ Any patient with suspected N1 disease after CT or PET scan should undergo mediastinal evaluation.

PREOPERATIVE EVALUATION

Standard preoperative evaluation in a patient undergoing mediastinoscopy includes a history and physical examination with a special focus on any history of neck or chest surgery, or a coexistent pathologic process such as a

TABLE 40-1 Relative Performance of Various Modalities of Mediastinal Lymph Node Assessment

Modality	Sensitivity (%)	Specificity (%)	NPV (%)	PPV (%)	Prevalence (%)
CT	57	82	83	56	28
PET	84	89	93	79	32

goiter or aneurysms of the aortic arch or innominate artery that may prevent safe access to the pretracheal space. Prior neck or sternal incisions, including prior mediastinoscopy, can complicate the initial dissection, but they are not absolute contraindications to the procedure. A retrospective series of patients undergoing both cervical mediastinoscopy and left anterior mediastinotomy with a history of sternotomy (half with left internal mammary artery coronary grafts) over two decades showed no differences in the efficacy or safety of these two procedures.¹²

Significant vascular calcification in the innominate artery can increase the risk of embolic events as this vessel is manipulated during the procedure. In addition, total atherosclerotic occlusion of the left common carotid artery can predispose a patient for stroke if the innominate artery supplying the right common carotid artery is compressed by the mediastinoscope. The evaluation should also note cervical spine arthritis because moderate neck extension is required for the procedure. Severe cervical kyphosis can make insertion of the mediastinoscope impossible. Patients should undergo laboratory workup as they might for any general anesthetic and should have

typical preparations for the small possibility of a blood transfusion.

POTENTIAL COMPLICATIONS OF MEDIASTINOSCOPY

Mediastinoscopy is a safe procedure when it is performed by experienced surgeons with knowledge of the surrounding mediastinal structures and a systematic deliberate method of tissue biopsy. Meticulous attention to hemostasis of minor bleeding can help to prevent subsequent bigger problems. A large series of more than 2000 procedures described a morbidity rate of 0.6% and a mortality rate of 0.2%.¹³ Possible major complications include major vessel hemorrhage (aorta, innominate artery, pulmonary artery, bronchial artery, vena cava, azygos vein), esophageal perforation, and stroke secondary to innominate artery compression in the setting of severe atherosclerosis. Other potential complications include left (and rarely right) recurrent laryngeal nerve injury, pneumothorax, wound infection, and tumor seeding of the neck incision.

For lung cancer patients undergoing restaging after induction chemoradiation therapy for N2 disease and without a history of prior mediastinoscopy (i.e., EBUS-TBNA determined N2 positivity before induction treatment), mediastinal changes from the treatment may be present. In one series that examined 51 patients who had mediastinoscopy after radiation therapy, approximately 10% of these patients had complications including two permanent recurrent laryngeal nerve injuries, an azygos injury that resulted in emergent right thoracotomy, and two aborted procedures that were truncated for safety.¹⁴ All but one of these patients experiencing complications had received levels of radiation therapy greater than or equal to 60 Gy. However, the overall performance of mediastinoscopy in terms of sensitivity, specificity, and negative predictive value were similar to metrics for mediastinoscopy done without prior therapy. Although this complication rate is higher than in other reported experience, it seems prudent to say that extra care should be taken when the patient has a known history of mediastinal radiation.

Reoperative mediastinoscopy for evaluating mediastinal nodes after induction therapy, inadequate first mediastinoscopy, or recurrent lung cancer can also be perilous, even among experienced surgeons. Although a series of almost 100 patients had a complication rate of 4%, the severity of these complications were higher than those seen in primary procedures, including biopsy of lung tissue, bronchial injury requiring patch repair, superior vena cava puncture requiring emergent right thoracotomy, and proximal innominate artery hemorrhage resulting in cardiac tamponade and death.¹⁵ Furthermore, in a review of patients undergoing restaging after induction therapy for stage IIIA NSCLC, the safer and less invasive alternatives offered with EBUS-TBNA and endoscopic ultrasound–fine needle aspiration (EUS-FNA; procedures to be discussed later in this chapter), demonstrated a lower false-negative rate and higher sensitivity than redo mediastinoscopy did.¹⁶ Reoperative

mediastinoscopy seems unnecessary given these safer alternatives.

SURGICAL TECHNIQUE

Standard cervical mediastinoscopy involves access of the middle mediastinal structures through a lighted, hollow, metal mediastinoscope introduced through a cervical incision. Large-bore venous access is warranted, and many anesthesiologists routinely place a right radial arterial catheter to monitor blood pressure and to watch for innominate artery compression during the procedure. Alternatively, some centers use a pulse oximeter probe on the right hand. Once patients are intubated, they are placed in the supine position with the neck gently hyperextended and supported with an inflatable bag or rolled blanket placed behind the shoulders (Fig. 40-7).

The endotracheal tube is brought out to the patient's right and kept as lateral and low in profile as possible to allow the surgeon to insert the mediastinoscope directly over the patient's chin in the midline. Care must be taken to avoid turning the patient's chin to the side as this can result in an off-center incision, which makes subsequent dissection more difficult and produces a suboptimal cosmetic result.

The entire sternum and anterior cervical areas are typically prepared and draped to facilitate a sternotomy for the rare event that massive bleeding is encountered.

FIGURE 40-7 ■ Patient and equipment positioning for video mediastinoscopy. The surgeon is shown looking across the operative field at the video monitor. *Top inset*, Diagram of a video mediastinoscope. *Bottom inset*, View of the patient's neck in extension, the incision site, and the support behind the patient's shoulders.

A 2.5-cm transverse incision is made one fingerbreadth above the sternal notch, and the platysma is divided in the line of the skin incision. The midline raphe between the strap muscles is opened vertically, and dissection is carried down to the trachea. On occasion, it is necessary to divide a low-lying thyroid isthmus or a thyroidea ima artery to reach the trachea. The pretracheal fascia is divided, and blunt finger dissection is undertaken to develop a plane anterior to the trachea in a caudal direction. A high-riding innominate artery can be seen in aneurysmal disease, in the setting of an enlarged station 2 (right) lymph node, or as an anatomic variant. The preoperative CT scan can provide a clue to this situation and help to avoid injury to the vessel during the initial dissection. The surgeon can obtain useful information during initial finger dissection of the pretracheal space, including the exact location of the ascending aorta and the angle and level at which the innominate artery crosses the field. In addition, firm pathologic lymph nodes alongside the distal trachea can be palpated and partially dissected free of surrounding tissue with the surgeon's fingertip.

The mediastinoscope is then inserted into the pretracheal plane that has been created (see Fig. 40-7). A standard mediastinoscope is a hollow, lighted, metal tube that permits only one individual to visualize the operative field. The introduction of video mediastinoscopy (Fig. 40-8; see also Fig. 40-7) has permitted all members of the team to visualize the operative field. This provides educational benefit for trainees, improves participation in the procedure (including the anticipation of the surgeon's needs), and allows better supervision during training. In addition, magnification, improved optics, and superior lighting have improved anatomic visualization (see Fig. 40-8). With a first assistant stabilizing the scope, the video mediastinoscope can be used by the surgeon to introduce two instruments into the field for bimanual dissection and hemostasis.

HIGH PARATRACHEAL DISSECTION

The major anatomic landmark of the high paratracheal level is the innominate artery (Figs. 40-9 and 40-10), which is seen as a pulsatile structure crossing anterior to the trachea. Station 2 lymph nodes lie to the left and right of the trachea at this level and above. Correlation of the endoscopic view at the station 2 lymph node level with sagittal anatomic structures as seen from the right chest is shown in Figure 40-11. Correlation of the endoscopic view with a transverse view of the mediastinal structures at this high paratracheal level is seen in Figure 40-12.

The operator's initial view of the paratracheal tissue often shows no obvious nodal tissue. Subsequent blunt dissection through the pretracheal tissue plane, assisted by careful use of the suction cautery tip, usually exposes the underlying lymph nodes. Dark pigmentation facilitates recognition of lymph nodes. It is recommended by the authors that blunt lymph node dissection be carried out to the point that the node bulges into the operative field (see Fig. 40-10). This technique helps to prevent inadvertent biopsy of other "dark" paratracheal

FIGURE 40-8 ■ Enhanced visualization with cervical video mediastinoscopy. (From De Leyn P, Lardinois D, Van Schil PE, et al: ESTS guidelines for preoperative lymph node staging for non-small cell lung cancer. *Eur J Cardiothorac Surg* 32:1–8, 2007.)

structures, such as the vena cava or the right brachiocephalic vein, which do not bulge into the field. In other words, lymph nodes should be recognized as three-dimensional structures; major veins remain two-dimensional dark surfaces after the dissection.

LOWER PARATRACHEAL DISSECTION

Dissection inferior to the innominate artery reaches the lower paratracheal area and station 4 lymph nodes, which

lie to the right and left of the trachea cephalad to the carina (Fig. 40-13). After blunt dissection of the paratracheal tissue permitting the nodes to bulge into the operative field, if there is any question about whether the tissue considered for biopsy is a lymph node, it is wise to aspirate the tissue first with a small-bore needle to rule out a vascular structure (Fig. 40-14). This maneuver, which can be used at any level, may also alert the operator to the presence of a major blood vessel lying immediately beneath the node to be sampled. This is important because inflammatory or malignant adhesions between

FIGURE 40-9 ■ Anatomic structures at the high paratracheal level as seen from the surgeon's position standing at the patient's head. *Ao*, Aorta; *INNOM. A*, innominate artery; *LCCA*, left common carotid artery; *LSCA*, left subclavian artery.

FIGURE 40-10 ■ View through the mediastinoscope at the high paratracheal level. Note the tracheal rings posteriorly and the innominate artery anteriorly. Also note the suction cautery dissection through the pretracheal fascia to allow the underlying station 2 lymph node located to the right of the trachea to bulge into the operative field.

the lymph node and the underlying major vessel can lead to avulsion injury to the vessel during vigorous lymph node biopsy. The non-lymph node structures lying to the right of the trachea at this level include the azygos vein, the superior vena cava, the mediastinal pleura, and the adjacent right upper lobe of the lung. The visceral pleura can appear darkly pigmented like a node, but the lung is characteristically seen to move behind the pleura with respiration. Structures lying to the left of the trachea at this level are the aortic arch, the left recurrent laryngeal

nerve, a bronchial artery branch from the aorta, and the esophagus. The esophagus lies posterior and to the left of the trachea at this level and can be mistaken for a white tumor-filled lymph node. It can be recognized by the longitudinal muscle fibers of its outer muscular layer.

The use of electrocautery should be avoided in the left lower paratracheal region to prevent inadvertent injury to the esophagus or paresis of the rarely visualized left recurrent laryngeal nerve lying in the tracheoesophageal groove. If esophageal injury is identified, the esophagus should immediately be repaired through a right or left thoracotomy. Most surgeons would prefer a right thoracotomy to repair the esophagus at this level. However, if there is preexisting lung disease in the left chest, a left thoracotomy may be used to address both. The site of esophageal injury usually lies directly medial to the aortic arch. With appropriate care, most surgeons will never face this rare complication. Correlation of the sagittal

and transverse anatomy at the station 4 lymph node level is shown in Figures 40-15 and 40-16, respectively.

CARINAL DISSECTION

The major anatomic landmarks of carinal dissection are widening of the trachea, the triangular tracheal cartilage

FIGURE 40-15 ■ Right mediastinoscopic view with plane passing through the mediastinal structures located at the lower paratracheal level. LBCV, Left brachiocephalic vein; RBCV, right brachiocephalic vein; RMB, right main bronchus; RPA, right pulmonary artery; SVC, superior vena cava.

FIGURE 40-16 ■ Transverse view of mediastinal structures at the lower paratracheal level. The pericardial recess (PCR) is a fluid-containing structure often mistaken for a lower mediastinal lymph node. The attenuated conformation of the structure along the outer wall of the ascending aorta (AAo) is a clue to its being a fluid-filled structure and not a node. Azyg v, Azygos vein; DAo, descending aorta; Dist. trach, distal trachea; E, esophagus; RLN, recurrent laryngeal nerve; SVC, superior vena cava; V, vertebra.

at the carina, the proximal left main bronchus, and the right pulmonary artery crossing anteriorly (Fig. 40-17). Because of its more posterior takeoff from the trachea, the proximal right main bronchus may be difficult to identify. The mediastinoscopic view of structures at the carinal level is depicted in Figure 40-18.

Identification of the triangular cartilage of the distal trachea helps to identify the level and prevents misidentification of the proximal left main bronchus as the trachea. Dissection at the carinal level must be performed with meticulous attention paid to the location of the right pulmonary artery. This pulsatile structure passes transversely across the field anterior to the airway.

FIGURE 40-17 ■ Anatomic structures at the carinal level as seen from the surgeon's perspective standing at the patient's head. Ao, Aorta; AZYG V, azygos vein; E, esophagus; LMB, left main bronchus; LSCA, left subclavian artery; RA, right atrium; RPA, right pulmonary artery; SVC, superior vena cava.

FIGURE 40-18 ■ View through the mediastinoscope at the carinal level. Note the widened tracheal diameter and the triangular tracheal cartilage just proximal to the subcarinal tissue containing station 7 lymph nodes. After blunt dissection and needle aspiration, as described earlier, a nodal biopsy is illustrated with a cup biopsy forceps. LMB, Left main bronchus; RMB, right main bronchus; RPA, right pulmonary artery.

Extensive blunt dissection of any suspected nodal tissue followed by needle aspiration before biopsy is vital (see Fig. 40-18).

seen sagittally from the right chest is shown in Figure 40-19. The transverse sectional anatomy at this level is shown in Figure 40-20.

NODE BIOPSY TECHNIQUE AND CLOSURE OF THE INCISION

As discussed previously, mediastinal node biopsy is initiated by dissection through the pretracheal fascia with a blunt suction cautery instrument (see Fig. 40-10). Next, the suspected lymph node is aspirated with a needle to confirm that it is not a vascular structure (see Fig. 40-14). Finally, a biopsy specimen is taken with a biopsy forceps

(see Fig. 40-18). Often, the first biopsy removes only the outer capsule of the node and exposes the underlying parenchyma, which can then be further sampled. If no node is seen at the desired station, it is often helpful to withdraw the mediastinoscope slightly and even to rotate it to see tissue lying more anterior or anterolateral to the trachea. These areas may reveal nodal tissue with further dissection. After biopsy, hemostasis is achieved with electrocautery or with temporary packing with long length gauze that is marked with a radiopaque thread (often described as a Vag Pack). Close attention must be paid to hemostasis throughout the procedure to maintain a clear field of vision. For a mild, persistent ooze of blood, withdrawal of the mediastinoscope a short distance and patient waiting will often achieve hemostasis because of simple tissue apposition. Rarely, an endoscopic clip applicator has been described as helpful to address a visible bleeding vessel. It is likely that many unsuccessful applications of endoscopic clips have been attempted and will never be reported; therefore, caution and careful consideration are strongly advised before resorting to such a strategy. Once hemostasis has been achieved at all levels, the mediastinoscope is removed and the wound is closed in several layers. The strap muscles are reapproximated with interrupted sutures vertically in the midline and the platysma muscle transversely; the skin is closed with a subcuticular suture. We obtain postprocedure chest radiographs of all patients to ensure the absence of a pneumothorax, a retained pack, or other visible abnormality. The patient can subsequently be discharged to home after standard postanesthesia care. Alternatively, after mediastinoscopy, the patient may be repositioned for pulmonary resection under the same anesthesia after frozen section evaluation of the lymph nodes by a pathologist.

MANAGEMENT OF MAJOR BLEEDING

A well-organized plan helps to address the possibility of major bleeding during mediastinoscopy. The first thing that is likely to happen is a complete loss of visualization. We recommend leaving the mediastinoscope in place and immediately packing the operative field with long gauze or a Vag Pack. This maneuver will temporarily contain most hemorrhage except that from systemic arteries. Attention is then turned to volume resuscitation and blood replacement if necessary. Waiting several minutes and then removing the packing often accomplishes hemostasis. If not, repeated packing preceded by a topical hemostatic agent such as oxidized cellulose can control venous and minor arterial bleeding without having to resort to median sternotomy or thoracotomy. Aortic, innominate artery, and bronchial artery injury adjacent to the aorta and major pulmonary artery injuries will not be contained with packing. Management should start with compression of the vessel with the mediastinoscope or removal of the mediastinoscope and compression of the vessel against the sternum with one's finger until either a median sternotomy (preferable in most situations) or a thoracotomy can be performed to allow direct vascular control.

EXTENDED MEDIASTINOSCOPY

We use the term *extended mediastinoscopy* to encompass techniques that go beyond the routine assessment of station 2, 4, and 7 lymph nodes in the mediastinum. A common misconception is that routine mediastinoscopy permits evaluation of the anterior mediastinum. However, a variation of mediastinoscopy known as *extended cervical mediastinoscopy* has been described that can access the anterior mediastinum as well as station 5 and 6 nodes in the aortopulmonary window (see Fig. 40-5). This procedure is started through the same cervical incision, but the surgeon subsequently creates a plane anterior to the innominate artery and posterior to the left brachiocephalic vein. Although the procedure has been described, it is rarely done, because of the inherent difficulty of the procedure involving dissection of major vessels in a confined anatomic space and the easy accessibility to the aortopulmonary window by an anterior mediastinotomy or thoracoscopy. In addition, the belief among many thoracic surgeons is that tumors of the left upper lobe with involvement of nodes in stations 5 and 6 (if limited to intracapsular spread and in the absence of other mediastinal node involvement) have a better prognosis with surgical resection than do tumors in other lobes with mediastinal node involvement and therefore do not have to be staged before lung resection.

Transcervical extended mediastinal lymphadenectomy (TEMLA) is also a mediastinal staging option for NSCLC and is performed through a 5- to 8-cm collar incision in the neck, enabling complete removal of all mediastinal nodal stations except for the pulmonary ligament nodes (station 9) and the most distal left paratracheal nodes (station 4L).¹⁷ In general, TEMLA is an open procedure performed partly with mediastinoscopy-assisted and video thoracoscopy-assisted techniques. The operative technique of TEMLA includes the elevation of the sternal manubrium with a special retractor and bilateral visualization of the laryngeal recurrent and vagus nerves. The stated benefits include a higher sensitivity and specificity compared with standard mediastinoscopy or video mediastinoscopy.

Video-assisted mediastinoscopic lymphadenectomy (VAMLA) is a mediastinoscopic dissection technique proposed for a radical mediastinal assessment and as an adjunct to open lymphadenectomy at the time of pulmonary resection.¹⁸ VAMLA dissection includes the en bloc resection of the subcarinal, right paratracheal, right tracheobronchial, and pretracheal compartments and dissection and lymphadenectomy of the left-sided tracheobronchial and paratracheal compartments. A specialized mediastinoscope with spreadable blades is used. A retrospective series comparing conventional mediastinoscopy to VAMLA demonstrated significantly increased mean number of lymph nodes sampled, improved sensitivity and negative predictive value, and even improved 5-year survival rates with VAMLA, presumably from improved detection and triaging of N2 disease.¹⁹ At this time, VAMLA also has a significantly higher complication rate (9.0% versus 4.1% in the conventional mediastinoscopy group), with the most common complication being dysphonia.¹⁹

FIGURE 40-21 ■ Image of the distal tip of a dedicated endobronchial ultrasound-transbronchial needle aspiration bronchoscope. The needle exits obliquely so the puncture site can be within the EBUS view. (From Ernst A, Feller-Kopman D, Herth FJ: Endobronchial ultrasound in the diagnosis and staging of lung cancer and other thoracic tumors. *Semin Thorac Cardiovasc Surg* 19:201–205, 2007.)

ENDOSCOPIC TECHNIQUES FOR MEDIASTINAL LYMPH NODE ASSESSMENT

Of recent significance has been the increasing use of EBUS-TBNA by surgeons and pulmonologists in the pathologic staging of the mediastinum. EBUS-TBNA can access mediastinal lymph node levels 1, 2R and 2L, 3, 4R and 4L, and 7. It can additionally sample hilar lymph nodes at levels 10R and 10L and 11 bilaterally, and part of level 12. EBUS uses an integrated, curvilinear ultrasound scanner at 7.5 MHz that produces a view through the bronchial wall into the mediastinal structures (Fig. 40-21).²⁰ A dedicated needle system is attached to the bronchoscope and advanced through the working channel. The needle, when advanced, can be seen in real time (Fig. 40-22).²⁰ The EBUS-TBNA bronchoscope handles differently from a conventional bronchoscope as the distal end is thicker and stiffer. The forward view is oblique instead of a straight ahead viewing angle. Once it is mastered, this endoscope allows lymph node biopsies under real-time ultrasound guidance. EUS-FNA can additionally provide access to level 8 and 9 lymph nodes (providing better posterior and inferior mediastinal lymph node access), leaving only the lateral aspects of levels 5 and 6 unreachable by either EBUS or EUS.^{21,22}

Although the option of an even less invasive method of mediastinal testing is attractive, especially in patients with bulky and suspicious mediastinal targets, there are still important gaps for optimal mediastinal staging with this technique. Although some studies have reported comparable results of EBUS-TBNA to mediastinoscopy

FIGURE 40-22 ■ Endobronchial ultrasound-guided puncture of a node in 10R position. The needle is clearly visible within the lesion. The system also allows color Doppler assessment of unclear structures. (From Ernst A, Feller-Kopman D, Herth FJ: Endobronchial ultrasound in the diagnosis and staging of lung cancer and other thoracic tumors. *Semin Thorac Cardiovasc Surg* 19:201–205, 2007.)

in determining final pathologic N staging, there are also some important exceptions that make this conclusion controversial.²³ While mediastinoscopy provides actual lymph node tissue for analysis, EBUS can only provide needle aspirates, raising the concern for higher false-negative rates, especially in marginally suspicious lymph nodes where micrometastases may be an issue. New techniques, such as EBUS-guided mini forceps biopsy, have been developed but are used for patients with concern for mediastinal diseases other than NSCLC.²⁴ One review of eight studies of EBUS-TBNA showed a similar sensitivity to video mediastinoscopy, but a clinically important average false-negative rate of 24% (range, 1%–37%).³ The average false-negative rate of mediastinoscopy in the same review was 10%.³ One series that examined EBUS-TBNA–negative patients with continued clinical suspicion of mediastinal nodal involvement based on CT or PET imaging found that subsequent mediastinoscopy revealed positive N2 disease in 28% of these patients.²⁵

Also of concern is the fact that many studies of EBUS-TBNA were performed on patients with discrete, enlarged mediastinal lymph nodes who represent a population with more obvious targets, thus artificially raising the EBUS-TBNA sensitivity.^{3,26} As an extension of the concern for the false-negative rate and unclear performance data in patients of advanced T stage (T2–T4) without obvious mediastinal lymph node involvement with EBUS-TBNA, the current recommendation by the American College of Chest Physicians is that when EBUS-TBNA provides a negative result in a setting of clinical suspicion, these findings should be confirmed by mediastinoscopy before definitive treatment.³ In prospective randomized trials comparing mediastinoscopy alone with EBUS-TBNA and EUS-FNA (followed by intraoperative surgical staging if no nodal metastases were detected by endosonography), it was found that the greatest sensitivity for mediastinal nodal metastasis and prevention of proceeding to inappropriate thoracotomy

was a *combined strategy* of endosonographic and surgical staging.^{27,28}

An additional role for these endosonographic techniques is in the setting of mediastinal reassessment after induction therapy when the initial diagnosis of N2 disease was made at mediastinoscopy. As mentioned earlier, redo mediastinoscopy remains a technically difficult and potentially dangerous procedure. Our preference is to establish the initial diagnosis of histologic N2 disease by EBUS-TBNA (where there are more likely to be larger targets that can be easily accessible) and limit video mediastinoscopy for restaging after induction chemoradiation therapy. Furthermore, it is strongly recommended that thoracic surgeons gain expertise in the endosonographic assessment of mediastinal lymphadenopathy, as these procedures can be performed sequentially in the operating room with the assistance of pathology interpreting the initial EBUS-TBNA findings.

SUMMARY

Although the anatomy of the mediastinum is presented in detail elsewhere in this book, it is reviewed here from a thoracic surgical perspective to highlight the radiographic and surgical anatomic subdivisions of the mediastinum that have been proposed. The simplest and most commonly used description is the three-compartment model proposed by Shields.¹ He divided the mediastinum into the anterior compartment, the middle (or visceral) compartment, and the posterior (or paravertebral) compartment. The anatomic limits of each compartment are shown in [Figure 41-1](#), and the structures contained within each compartment are listed in [Table 41-1](#). Locating a mass in the anterior mediastinum allows a differential diagnosis to be generated that is based on the knowledge of the normal structures in that compartment. From the perspective of thoracic surgery, this approach best allows the appropriate diagnostic and therapeutic procedures to be selected.

[Box 41-1](#) contains an extensive list of the pathologic conditions that can appear as a mass in the anterior mediastinal compartment. By far, the three most common of

these are thymoma, lymphoma, and teratoma (and other germ cell tumors).

THYMIC TUMORS

Lesions of the thymus account for approximately 50% of anterior mediastinal masses in adults and are thus of great importance. Although lymphomas and germ cell tumors of the anterior mediastinum often involve the thymus or actually arise from cells within the thymus (or both), these are most appropriately discussed as a group separate from thymic tumors and are usually classified separately. The thymic masses discussed in this section are listed in [Box 41-2](#).

Thymoma

Thymomas are the most common thymic tumor, and approximately 95% are located in the anterior mediastinum. They are of surgical interest both because excision is

TABLE 41-1 Components of Mediastinal Compartments*

Anterior	Visceral (Middle)	Paravertebral (Posterior)
Thymus	Pericardium/heart	Sympathetic chain
Internal thoracic vessels	Great vessels	Proximal intercostals: nerve, artery, and vein
Internal thoracic lymph nodes	Trachea	Posterior paraesophageal lymph nodes
Prevascular lymph nodes	Proximal right and left main-stem	Intercostal lymph nodes
Fat and connective tissue	Esophagus	
	Phrenic nerve	
	Thoracic duct	
	Proximal azygos vein	
	Pretracheal lymph nodes (levels 2, 4, and 7)	
	Pleuropericardial lymph nodes	
	Fat and connective tissue	

*The nodal basin draining the anterior chest wall, and the female breast lie in the anterior compartment, whereas the majority of those draining the lung that are important in lung cancer staging lie in the visceral compartment.

the primary therapy and because of their interesting association with myasthenia gravis (MG), the clinical course of which can be favorably influenced by thymectomy.

Thymomas may be completely encapsulated or invasive. Large series have demonstrated the incidence of encapsulated lesions to be between 40% and 70%, and that of microscopic or grossly invasive lesions to be between 30% and 60%. Although local invasion is usually limited to the capsule or to immediately adjacent structures, spread to more distant sites within the chest does occur, particularly to the pleura, diaphragm, and mediastinal lymph nodes. Aggressive thymomas have been reported to be associated with distant metastases in as many as 30% of patients at high-level referral centers,² but most broad studies report distant metastasis to be rare (<5%).

Pathology

Thymomas are derived from thymic epithelial cells, but most contain varying mixes of epithelial cells and

lymphocytes.³ Traditional histologic classifications have therefore grouped thymomas according to cytologic make-up: (1) predominantly lymphocytic, (2) predominantly epithelial, and (3) mixed.⁴ There is also a recognized spindle-cell variant of the epithelial subtype. Approximately 50% of the tumors are of the mixed variety, with the remainder split between the epithelial and lymphocytic subtypes. Unfortunately, these subtypes have little prognostic significance aside from the generally better prognosis of the spindle-cell variant, and thus more recent investigators have proposed alternative histologic classification schemes (discussed later).

Of clinical significance is the fact that it may be more difficult to establish the diagnosis of thymoma from a small sample (e.g., by needle biopsy) of a lymphocyte-predominant thymoma versus the other subtypes because of its microscopic similarity to lymphoma. Immunohistochemical staining for cytokeratin often aids in making the diagnosis, because antibodies to this protein are present in 95% to 100% of thymomas.⁵ Chromogranin staining allows for differentiation between thymoma and thymic carcinoid (the former being negative and the latter being positive for chromogranin).

Classification

No tumor-nodes-metastasis (TNM) classification has been found to be of value for staging thymomas.

The most widely used clinical classification scheme is that proposed by Masaoka and colleagues in 1981⁶ (Table 41-2). This scheme takes into account the gross presence or absence of encapsulation, and fixation or invasion, into adjacent structures as identified at the time of surgery. It also recognizes that a grossly well-encapsulated tumor may be found to have invasion through the capsule at microscopic examination. In the years since it was originally proposed, the Masaoka system, or later variations of it, have been found by numerous authors to have prognostic significance.

In 1985, Marino and Müller-Hermelink⁷ proposed a histologic classification that has come to be known as the Müller-Hermelink (MH) classification. This scheme divides thymomas into cortical, medullary, and mixed types. The cortical type contains medium to large

TABLE 41-2 Classification Schemes for Thymoma

Stage	Masaoka	WHO*
I	Encapsulated; tumor may invade into, but not through, capsule microscopically	Type A (spindle cell, medullary)
II		
IIA	Microscopic invasion into thymus or fat or adherent to, but not through, pleura or pericardium	Type AB (mixed) Type B
IIB	Macroscopic transcapsular invasion	B1 (lymphocyte-rich, predominantly cortical) B2 (cortical)
III	Macroscopic invasion of neighboring organs (pericardium, great vessels, lung)	B3 (epithelial, well-differentiated thymic carcinoma)
IV		
IVA	Pleural or pericardial dissemination	Type C (thymic carcinoma)
IVB	Lymphogenous or hematogenous metastasis	

*In the World Health Organization (WHO) column, terms in parentheses represent nomenclature from previous histologic classifications that most closely approximate the current classification category.

Health Organization (WHO) has adopted a classification system based on the MH criteria (see Table 41-2).¹² Currently the state of the art is to use a combination of the WHO histologic systems in combination with the Masaoka staging system to provide the most precise prognostic information.

Presentation

Most patients with thymomas present at an age older than 40 years. There is no major predominance in men or women. Approximately 50% of patients are asymptomatic; the remaining patients have either local symptoms (e.g., pain, dyspnea, cough, hoarseness) resulting from locally invasive tumors or systemic symptoms of one of the associated systemic diseases.

epithelial cells of characteristic appearance, and usually abundant lymphocytes. The medullary type contains small to medium cells with different features and fewer lymphocytes. The former tend to be of higher clinical stage, whereas the latter tend to be of lower invasiveness. Many investigators have generated data in support of the prognostic significance of the MH classification,⁸⁻¹¹ showing that the medullary type has the best and the cortical type the least favorable prognosis. The World

Association with Myasthenia Gravis

Patients with thymomas may present with a number of associated diseases, largely autoimmune in etiology, but the most common associated illness is MG. Accumulated experience suggests that 5% to 15% of patients with MG are found to have thymomas, and that 30% to 50% of thymomas are associated with clinical MG. Notably, the disease may develop later, even after thymoma resection, if it is not present at the time of discovery of the thymic tumor. For this reason, it is essential that a complete thymectomy be performed as part of the resection of any anterior mediastinal tumor that may be a thymoma. Because MG is an autoimmune disease caused by anti-acetylcholine receptor (anti-AChR) antibodies, its relationship to thymoma and treatment by thymectomy appears to be related to the role of the thymus in the creation of these antibodies.^{13,14}

This association has a long and very interesting history that is beyond the scope of this chapter. Highlights, however, include the first description by Schumacher and Roth in 1912 of improvement in MG after thymectomy,¹⁵ the more systematic evaluation of this concept by Blalock and coworkers in the late 1930s,¹⁶ and the subsequent controversy over whether the morbidity and rare mortality rates associated with the procedure justified the chances of a remission from MG. Only in the late 1960s and 1970s did thymectomy for MG in the absence of thymoma gain wide acceptance, because improvements in perioperative care reduced the morbidity of the procedure and the benefits became clearer. Convincing data suggest that patients with MG who are treated with thymectomy have a higher remission rate than historical controls treated by medication alone. A multinational randomized study sponsored by the National Institute of Neurological Disorders and Stroke to definitively establish this concept is currently ongoing.¹⁷ Results are eagerly awaited in the coming years.

Association with Other Diseases

Box 41-3 lists MG and the other systemic, autoimmune disorders most commonly associated with thymoma. Two percent to 15% of patients with thymoma have some type of cytopenia. The most common type is pure red-cell aplasia thought to result from an abnormal IgG antibody that inhibits red-cell synthesis. Most patients with this

disease have the favorable, spindle-cell type of thymoma.¹⁸ Approximately one-third of patients with aplasia demonstrate improvement after thymectomy.¹⁹ Hypogammaglobulinemia occurs in less than 5% of patients with thymoma, those being principally older patients. This disease generally does not respond to thymectomy and the prognosis is poor. Of the other autoimmune disorders that occur in association with thymoma in lower frequencies, lupus appears to be the most common; again, resection does not appear to have an impact on the clinical course.

The Anterior Mediastinal Mass That Might Be Thymoma

Imaging. Radiologic studies play a central role in the evaluation of thymoma. Because many patients are asymptomatic at presentation, a widened mediastinum or loss of the normal anterior clear space on the lateral film of a routine chest radiograph may be the first sign of disease. In such a patient, a computed tomography (CT) scan of the chest with intravenous contrast medium should be obtained as the next step. Patients who present with MG or another of the disorders that may be associated with thymoma should also have a chest CT scan.

Although no appearance on CT scan is definitively diagnostic of thymoma, a well-circumscribed, solid anterior mediastinal mass in an adult older than 40 years, without low-density areas that suggest the cystic and fatty components of a teratoma, is very likely to be a thymoma (Figs. 41-2 and 41-3). The presence of calcification is not particularly helpful, because both thymomas and teratomas may contain calcium. In some cases, lymphoma will be the obvious diagnosis on the basis of adenopathy outside of the anterior mediastinum or “B” symptoms, but in the absence of these findings, differentiating a thymoma from a lymphoma may be difficult. It is often possible to suspect one over the other only on the basis of the thymoma patient’s typically more advanced age. Magnetic resonance imaging (MRI) provides useful additional information only when the fluid or fatty nature of

BOX 41-3 Systemic Diseases Most Commonly Associated with Thymoma

- Myasthenia gravis

- Ulcerative colitis

FIGURE 41-2 ■ Characteristic CT appearance of a noninvasive thymoma: a well-circumscribed, solid anterior mediastinal mass.

FIGURE 41-3 ■ (A) Posteroanterior and (B) lateral chest radiographs from a 21-year-old man showing a large mediastinal mass adjacent to the right cardiac border. This appearance is characteristic of a mediastinal teratoma. The CT scan (C) shows a complex cystic mass with solid components, including fat and calcification consistent with a diagnosis of teratoma. In the absence of metastatic disease, the final differentiation between teratoma and teratocarcinoma can be made only by pathologic review. (A and B, Courtesy Wallace T. Miller, Jr., Hospital of the University of Pennsylvania, Philadelphia.)

a component of the tumor is not clearly defined by CT scan or when a vascular structure (e.g., an aneurysm) is suspected and has not been clearly ruled out by the contrast CT study.

The chest CT scan also provides information about a putative thymoma's local and regional spread. Loss of planes between the tumor and normal structures may suggest direct invasion, and visceral or parietal pleural deposits may be visible as well. The presence of such signs of local aggressiveness should steer the surgeon toward biopsy rather than primary resection, given the recent data suggesting improved results with neoadjuvant chemoradiotherapy before operation in aggressive thymoma and thymic carcinoma.²⁰⁻²² The role of positron emission tomography (PET) in thymic tumors is not well-defined. It has been shown that PET may be useful for predicting the grade of malignancy according to histologic subtype.²³

Serum Studies. All male patients with an anterior mediastinal mass should have serum testing for α -fetoprotein (AFP), β -human chorionic gonadotropin (β -hCG), and lactic dehydrogenase. Although these levels are normal in patients with mature teratoma, those with malignant germ cell tumors have significant elevations; thus, the

clinician should establish this diagnosis and rule out thymoma.

Evaluation for Myasthenia Gravis. All patients with suspected thymoma should be carefully questioned about muscle weakness or ocular or bulbar signs of MG. The diagnosis of MG classically requires a characteristic history or physical findings, or both, as well as two positive diagnostic tests. Diagnostic testing for MG includes pharmacologic, serologic, and electrodiagnostic studies. Unfortunately, no single diagnostic test can rule out MG with certainty in patients with thymoma. If there is the slightest suggestion of MG at a patient's initial presentation, the patient should undergo additional testing preoperatively under the direction of an experienced neurologist.

Depending on the disease severity, patients with MG may require medical optimization before surgery by some combination of cholinesterase inhibitors, steroids, gamma globulin, and plasmapheresis. In addition, drugs that may exacerbate the symptoms of MG must be avoided (e.g., aminoglycosides, certain inhalation anesthetics, iodinated radiographic contrast). Establishing the preoperative forced vital capacity for comparison with values obtained serially postoperatively can be useful for

determining the appropriateness of extubation in patients with MG after general anesthesia and as an early sign of postoperative deterioration that can then be rapidly addressed.

Biopsy. Typically, the clinician proceeds directly to resection of a discrete anterior mediastinal mass in any of the following situations: (1) the CT or MRI shows features pathognomonic of teratoma; (2) the patient is older than 40 years, without clinical signs or symptoms of lymphoma and with normal AFP and β -hCG; or (3) the mass is associated with MG. In most other instances, biopsy is indicated because, despite the history, physical examination, imaging, and serum studies, a mass still remains that could represent thymoma, lymphoma, or teratoma.

There is controversy regarding whether the biopsy should be done by core-needle biopsy,²⁴ anterior mediastinotomy (Chamberlain procedure), transcervical mediastinotomy, or video-assisted thoracoscopic surgery (VATS) (see Surgical Approaches to Biopsy, discussed later). Needle biopsy has the disadvantage that optimal tissue may not be obtained, and the availability of pathologists adept at differentiating lymphoma from thymoma and among the various types of lymphoma by cytology and flow cytometry is required. Although mediastinotomy almost always provides adequate tissue for diagnosis, there is a theoretical risk (unproven) that thymoma cells may be spread, rendering a previously contained tumor less clearly resectable (an even greater concern for VATS). We favor mediastinotomy when lymphoma is the leading clinical diagnosis, but we believe that core-needle biopsy is required for tumors that are more likely to be thymoma or germ cell tumor (e.g., radiographically aggressive thymoma in which neoadjuvant protocols might be considered).

Treatment

Surgery. Complete surgical resection along with complete thymectomy is the optimal management for thymoma that is not known preoperatively to be invasive. The technique is detailed later in this chapter.

Adjuvant Therapies. For aggressive thymomas, neoadjuvant chemotherapy before resection should be considered because thymomas are chemotherapy-sensitive malignancies. The response rate to these regimens, which generally contain cisplatin, is high, and the rate of complete resection appears likely to be improved by such an approach. These patients should probably also receive postoperative radiotherapy. Some neoadjuvant protocols have included radiotherapy.

Postoperative radiation therapy is certainly indicated in cases of incomplete resection and likely after complete resection of Masaoka stage III thymomas. Because the rate of recurrence of completely resected stage I tumors is less than 5%, these patients are generally not considered for adjuvant radiation. Adjuvant radiotherapy for completely resected stage II thymoma is more controversial. We²⁵ and others²⁶ have presented data that strongly suggest that postoperative radiotherapy is not indicated

in stage II disease, where the surgeon has no uncertainty about resection margins.

Outcome

The outcome for patients with thymoma is stage specific. Patients with completely resected Masaoka stage I thymomas have an excellent prognosis, with an expected recurrence rate of less than 5%. The 10- and 20-year survival rates are 99% and 90%, respectively.²⁷ As the stage increases, the recurrence rates increase and the survival rates decrease. Patients with stage II thymomas treated by complete resection with or without postoperative radiation therapy have recurrence rates as high as 20%.^{26,28} The 5- and 10-year survival rates are 70% to 90% and 55% to 85%, respectively.^{28,29} Long-term data from Japan show better 10- and 20-year survival rates of 94% and 90%, respectively.²⁷ The 5-year survival rates for patients with resected stage III tumors decreases to approximately 50%.³⁰ It is clear that patients with stage III disease who are able to undergo complete resection—even if that requires resection of great vessels or contiguous lung—have substantial cure rates.

What is less clear is whether patients with advanced stage III and IV disease who undergo a marginally complete resection have an improved prognosis compared with those who undergo biopsy alone. The MD Anderson Cancer Center (Houston, Tex.) reported their results in a patient cohort ($N = 22$) of this sort with advanced-stage thymoma in a recent phase 2 study evaluating tumor resectability after induction chemotherapy followed by surgical resection, radiation therapy, and consolidation chemotherapy.³¹ Ten patients had stage IVA disease, and the results are encouraging. With a median follow-up time of 50 months, 18 of 19 patients who completed the multidisciplinary approach were disease-free. The progression-free survival rates were 77% at 5 years and 77% at 7 years. Comparisons of the results of this study with other studies of multimodality therapy of advanced thymoma that did not include surgical resection strongly indicate that surgical resection should be included if there is any chance for a complete resection.

Historically, the presence of thymoma was believed to affect the outcome adversely after thymectomy for MG. Several modern studies, however, suggest that this is not the case. A review from the Toronto General Hospital revealed no significant difference in the complete response rate or postoperative Osserman grade of patients with MG undergoing thymectomy, with or without thymoma.³² The complete remission rate of MG at 5 years after thymectomy was 36% with or without thymoma.

Thymic Carcinoma

Thymic carcinomas are rare invasive epithelial malignancies. A clinicopathologic study of 60 cases of thymic carcinoma revealed an overall 5-year survival of 33%.³³ Histologically, this group consists of a number of different cell types. They are unified, however, by their unequivocal malignant appearance on light microscopy. Although there is no formalized staging system, division

of patients into those with low-grade histology and those with high-grade histology does have prognostic significance. Low-grade tumors include squamous, mucoepidermoid, and basaloid carcinomas. The high-grade tumors include sarcomatoid and clear-cell carcinoma. The median survival time for patients with low-grade histology is 29 months, compared with 11 months for patients with high-grade histology.³⁴ Effective therapy of thymic carcinoma requires a multimodality approach, which typically includes induction therapy followed by resection (if possible), with postoperative radiation therapy if it was not included preoperatively. Unfortunately, most patients have recurrence, either locally or at distant sites, and die of their disease. Multiple neoadjuvant chemotherapy protocols have been proposed for patients presenting with clearly unresectable disease. To date, the numbers are too small and the results too variable to determine whether this approach converts these patients into operative candidates or affects their overall outcome.³⁵

Neuroendocrine Tumors of the Thymus

Neuroendocrine tumors of the thymus include thymic carcinoid and small cell carcinoma of the thymus. These tumors are related biochemically by the presence of amine precursor uptake and decarboxylation cells and may actually represent a spectrum of the same abnormality.

Thymic carcinoid occurs more frequently in men than in women. One-third of patients present with Cushing syndrome because of ectopic adrenocorticotrophic hormone production. This portends a very poor prognosis. The treatment of thymic carcinoid is complete excision, and the overall cure rate is very low. The role of multimodality therapy is undefined.

Small cell carcinoma of the thymus is very uncommon. A 20-year review of extrapulmonary small cell carcinoma at the Mayo Clinic revealed only three cases of a total 54 patients.³⁶ This tumor, however, is extremely aggressive. It is treated with chemotherapy alone or in combination with radiation. Like small cell carcinoma of the lung, it is usually responsive to initial chemotherapy, but the response is often not durable.

Other Abnormalities of the Thymus

Hyperplasia

The infant thymus is a large, pyramid-shaped gland that occupies a significant portion of the anterior mediastinum. In contrast, the adult thymus is an involuted organ consisting mostly of adipose tissue surrounded by a capsule. The gland shrinks slowly over the years. In true thymic hyperplasia, the gland is generally enlarged in both size and weight (for the patient's age), but the key feature is that histologically the gland is hyperplastic, with more cellularity and less adipose tissue. The presentation of thymic hyperplasia is along a spectrum ranging from usual adult presentation of an incidentally discovered, asymptomatic mass to the giant mass in an infant causing respiratory compromise due to tracheal

compression. Thymic hyperplasia can certainly be seen in association with MG, and it is believed likely to be causally related to MG, but it is also commonly seen in association with Graves disease and after a severe illness or a course of steroid therapy—so-called “thymic rebound.” All of these must be considered before recommending surgical intervention for someone with an “enlarged” thymus.

Unfortunately, no one has ever carried out a definitive study establishing what constitutes “normal” thymic size at various ages. The thoracic surgeon is therefore typically left to use judgment and experience to decide whether a given referred patient's thymus is “normal” or “enlarged.” A study from the senior author has shown that an asymptomatic patient with diffuse thymic enlargement and no discrete mass can be safely observed without resection.³⁷ Others have also suggested that normal thymuses are perhaps too often removed when a patient presents with no other problem than a gland that is felt to be modestly enlarged.³⁸

Thymolipoma

Thymolipomas are distinguished from simple mediastinal lipomas by their location in the thymic capsule. Histologically, these neoplasms contain mature adipose cells as well as normal thymic components. Interestingly, thymolipomas can be associated with thymic paraneoplastic syndromes such as red-cell aplasia, aplastic anemia, and hypogammaglobulinemia like thymuses (see previous discussion). The treatment of thymolipoma is excision.

Thymic Cysts

Mediastinal thymic cysts account for less than 0.2% of anterior mediastinal masses.³⁹ They are often asymptomatic and are usually discovered incidentally. Most are unilocular, and they must contain thymic tissue within the cyst wall to confirm the diagnosis. As a unique entity, they are inconsequential and completely benign. Removal is only indicated when it is necessary to rule out other entities, such as thymoma with cystic components (i.e., cystic thymoma). Unfortunately, these diagnoses are not easily differentiated on radiographic grounds. Excision may be required; it yields a definitive diagnosis and completes treatment.

GERM CELL TUMORS

Germ cell tumors (GCTs) comprise a group of neoplasms that usually arise in gonadal tissue. The anterior mediastinum is the most common extragonadal location for GCTs, which account for 15% to 20% of all anterior mediastinal masses. These tumors are divided into benign and malignant lesions.

Benign Mediastinal Teratoma

Benign mediastinal teratoma accounts for 60% of mediastinal GCTs. It is usually asymptomatic in the adult but can cause cough or discomfort/pain when large. Children

are more likely to present with symptoms caused by airway compression. On CT scan, the mass is well-circumscribed and may contain calcification. It usually shows variable enhancement because of the presence of different tissue types including fat, muscle, bone, and cystic components (see Fig. 41-3). Curative treatment consists of complete excision, classically via median sternotomy, but now probably more commonly by VATS or robotic approaches. Thoracosternotomy may be required for giant tumors.

Malignant Mediastinal Germ Cell Tumors

The malignant mediastinal GCTs are divided into seminomatous and nonseminomatous tumors. Seminomas account for 40% of these tumors, and nonseminomas account for 60%. The nonseminomas include embryonal cell carcinoma, choriocarcinoma, yolk sac tumors, and teratocarcinomas. These tumors are generally diffuse—not discrete—anterior mediastinal masses, and they frequently invade surrounding structure, causing symptoms.

The malignant GCTs are much more common in males, but they have been reported in females.⁴⁰ The preoperative evaluation of these patients includes a complete physical examination, including testicular examination in male patients to be certain these are primary mediastinal tumors and not metastases. Radiographic studies should include a CT scan of the chest, abdomen, and pelvis. Serum AFP, β -hCG, and lactate dehydrogenase levels should be obtained.

Patients with pure seminoma have normal AFP and usually a mild elevation of β -hCG. A pure nonseminomatous GCT may have elevated AFP (in 50%) and/or β -hCG (also in approximately 50%). Elevated AFP is most closely associated with yolk sac tumors, whereas elevation of hCG is more closely associated with choriocarcinomas. The differentiation between the seminomatous and nonseminomatous germ cell tumors has important prognostic and therapeutic implications. Like testicular seminomas, the pure mediastinal seminomas are extremely radiosensitive, but today the primary treatment is more commonly cisplatin-based chemotherapy alone, which also yields very high response rates, and about 80% of patients with pure seminomas are cured.⁴¹ Residual masses with PET activity and histopathologic residual cancer after treatment of seminoma may be resected if possible in preference to adding radiation. Alternatively, chemotherapy can be used. The optimal treatment of a residual mass remains debatable.⁴²

After confirmation by needle biopsy, nonseminomas are usually treated with three-drug chemotherapy (etoposide, ifosfamide, and cisplatin). Traditionally, surgical resection was reserved for a residual mass after treatment that was associated with normalization of serum markers (this indirectly suggesting a strong response to treatment, translating to a greater chance of complete resectability). This approach, however, has been changing. Researchers at Indiana University reviewed their 25-year experience with treated mediastinal nonseminomatous germ cell tumors in 158 patients.⁴³ With a median follow-up of 34

months, they reported a 62% overall survival. Multivariate analysis revealed that, among other variables, pathologically identified complete tumor necrosis after chemotherapy was an independent predictor of survival. Operative risks for nonseminomatous germ cell tumors appear to be improved with the use of chemotherapy regimens that did not contain bleomycin. Data from Memorial Sloan-Kettering⁴⁴ and other institutions⁴⁵ suggest that all patients with a residual mass after chemotherapy should undergo resection even if their markers remain elevated. These studies revealed that postchemotherapy serum marker levels correlated poorly with pathologic evidence of disease. Further, there were no effective second-line chemotherapy regimens, and long-term survival differences did not exist in patients with presurgical elevated markers versus patients with normal markers.

LYMPHOMAS

Both Hodgkin disease and non-Hodgkin lymphomas can appear as anterior mediastinal masses. The diagnosis is usually suspected on clinical history and CT scan. We recommend surgical biopsy over needle biopsy as the most efficient method of obtaining a precise diagnosis when lymphoma is suspected (see previous discussion), although in many institutions now there is sufficient expertise with flow cytometry to obtain a diagnosis in most cases with a core-needle biopsy specimen only. Surgical approaches to biopsy include cervical mediastinoscopy, anterior mediastinotomy, and, less commonly, thoracoscopy. It is imperative that the surgeon work in conjunction with the pathologist at the time of surgery to ensure that adequate tissue is obtained. The diagnosis of Hodgkin disease is confirmed by the presence of Reed-Sternberg cells. The diagnosis and characterization of the non-Hodgkin lymphoma rely on both light microscopy and cell-surface markers. Flow cytometry requires fresh (unfixed) tissue, so the surgeon must ensure that not all of the biopsy tissue is placed in formalin.

Controversy persists over the sensitivity and specificity of the CT scan and PET scan in determining the composition of residual masses after chemotherapy and radiotherapy for lymphoma. Some clinicians advocate multiple core-needle biopsies in this setting, but this is subject to sampling error. Surgical biopsy clearly is more sensitive and is indicated commonly.

SUBSTERNAL THYROID

Substernal thyroid and ectopic thyroid tissue can appear as an anterior mediastinal mass. In most cases of substernal thyroid, an enlarged thyroid gland is palpable in the neck. Often, a chest radiograph shows deviation of the trachea. We have found that a CT scan without contrast is the single most useful test in differentiating substernal thyroid from other mediastinal masses. Because of its iodine content, substernal thyroid tissue shows enhancement on a noncontrast CT scan, and this usually confirms the diagnosis. The majority of substernal thyroids are

goiters, but a benign process versus a malignant process cannot be differentiated radiographically. The vast majority of substernal goiters are able to be removed via a cervical approach. This is possible because the blood supply of the superior and inferior thyroid arteries originate in the neck. In some instances, a partial sternal split is required to provide adequate room for delivery of the gland from its substernal location. Infrequently, tracheal stenting, or even resection with primary anastomosis, is required to correct tracheomalacia caused by compression, or for direct tracheal invasion in the case of malignant substernal thyroid neoplasms. This should be performed as a single-stage operation at the time of thyroid resection.

HYPERFUNCTIONING MEDIASTINAL PARATHYROID ADENOMA

Ectopic parathyroid glands are not infrequently located in the mediastinum—typically embedded with the thymus gland. These patients exhibit primary hyperparathyroidism after unsuccessful neck exploration. Before mediastinal exploration is undertaken, localizing studies should be performed. Nonfunctional anatomic studies such as CT and MRI may reveal a well-defined mass. Technetium-99m-sestamibiscintigraphy, however, is the most useful study to localize hyperfunctioning ectopic parathyroid adenomas. In rare cases, no clear ectopic gland is identified, and “blind” resection of the thymus may be indicated. The treatment for an ectopic mediastinal parathyroid adenoma is resection. This is performed via a transcervical approach (i.e., a transcervical thymectomy [TCT]) via a median sternotomy or by thoracoscopy. Resection involves removal of the thymus and surrounding fat to include the adenoma. Intraoperative use of rapid parathyroid hormone levels can be used to confirm the successful localization and removal of the adenoma. The presence of parathyroid tissue should be at a minimum confirmed by frozen section examination. If the transcervical or VATS approach is selected and there is no normalization of intraoperative parathyroid hormone, or if parathyroid tissue cannot be confirmed pathologically, the surgeon should convert to a median sternotomy.

SURGICAL APPROACHES TO BIOPSY

Chamberlain Procedure (Anterior Mediastinotomy)

This procedure is usually performed under general anesthesia, but it can be performed under local anesthesia if required. The patient is placed in the supine position with arms tucked. A 5-cm, horizontally oriented incision is made just lateral to the sternomanubrial joint over the second costal cartilage. The pectoralis muscle fibers are split from the sternochondral to the costochondral junction. The second cartilage is removed subperichondrially, and the pleura is gently swept laterally to avoid inadvertent pneumothorax. Care is taken to avoid injury to the internal thoracic artery and vein, but sometimes they

must be divided to gain sufficient exposure. Biopsy is performed under direct vision with a scalpel or biopsy forceps. During closure, the perichondrium should be reapproximated to promote regrowth of normally shaped cartilage.

Transcervical Biopsy (Cervical Mediastinotomy)

Transcervical biopsy is performed through a transcervical collar-type incision. The exposure is identical to that described later for TCT, and it is facilitated by use of the Cooper retractor. Once exposure is obtained, tissue can be procured directly with biopsy forceps or scalpel. We have found this approach to be particularly useful to biopsy lesions directly beneath the sternum that would be difficult to reach by a Chamberlain procedure and thus might otherwise require a sternotomy.⁴⁶

Thoracoscopic Biopsy

VATS can be used for biopsy of anterior mediastinal masses, but in most situations there are simpler and more direct approaches. The anterior mediastinum can be reached from either the left or the right hemithorax, and the side should be selected on the basis of the predominant location of the mass. A 30-degree thoracoscope facilitates visualization of the anterior mediastinum. The thoracoscope is introduced generally through the fourth intercostal space at approximately the anterior axillary line. A simple biopsy can often be performed through this single port, extended to about 2 cm in length, by placing the biopsy forceps adjacent to and parallel with the camera. Sometimes one additional working port is needed. The anterior compartment is accessed by incising the pleura anterior to the phrenic nerve. The connective tissue is gently swept away and the lesion identified and biopsied—typically with mediastinoscopic biopsy forceps.

It is our opinion that the VATS approach is more cumbersome and associated with greater risks than either the anterior mediastinotomy or the transcervical approach. Injury to a phrenic nerve, though rare, is a catastrophe. Spillage of tumor during biopsy (which is probably impossible to avoid using the VATS approach) may cause contamination of the pleural space, facilitating, in the case of thymoma, its natural means of spreading. Finally, this approach requires single-lung ventilation, which adds an additional level of complexity to the anesthetic management, especially in patients with large masses and tracheal compression.

Extended Mediastinoscopy

In 1987, Ginsberg and colleagues reported the use of extended cervical mediastinoscopy in the staging of lung cancer.⁴⁷ This advanced technique allows placement of a mediastinoscope into the anterior compartment through a standard cervical mediastinoscopy incision. This involves the creation of a tunnel between the origin of the innominate artery and the left carotid artery. The tunnel is created by careful digital dissection, the mediastinoscope is then reinserted and advanced anteriorly

toward the left into the tunnel, and the target lesion is identified and biopsied. This technique requires considerable experience and carries the risk of significant bleeding because of the proximity of the aorta and pulmonary artery. Unless the surgeon has been specifically trained in this technique, most anterior mediastinal masses are more safely and easily approached via anterior or cervical mediastinotomy, as described previously.

THERAPEUTIC SURGICAL PROCEDURES: TECHNIQUES OF THYMECTOMY

The main surgical procedure carried out for tumors of the anterior mediastinum is thymectomy, because thymoma is the most common tumor in this area and demands complete extirpation of the gland. Only if there is certainty preoperatively that the tumor is other than thymoma (generally a teratoma) should the surgeon attempt to explore the anterior mediastinum and resect the tumor alone without the entire adjoining thymus. In this circumstance, a frozen section should always be obtained to confirm the preoperative diagnosis so as not to inadvertently perform less than a complete thymectomy for thymoma.

The reasons for performing a total thymectomy in patients with thymoma include that:

- It promises the widest possible resection margin through a natural anatomic plane, and
- Patients with thymoma may develop MG well after their operation. Because total thymectomy appears to improve the course of MG, it should be performed during all thymoma operations.

Thymectomy by Median Sternotomy

Median sternotomy is still likely the most widely used approach to thymectomy. Although a full sternotomy is

typical, partial upper sternotomy with extension of the bony incision into the third or fourth intercostal space also has its advocates.⁴⁸ We find that this is no less painful than sternotomy and substantially limits exposure. Adjacent structures to which the tumor is adherent must be resected en bloc. This often includes pleura, pericardium, and, in more aggressive tumors, the innominate vein (which may be resected without reconstruction), the superior vena cava (requiring reconstruction), and/or the lung. Both pleural spaces should be widely opened by two incisions in the mediastinal pleura on each side: one just anterior to the phrenic nerve and one just posterior to the chest wall. In all procedures, the upper thymic poles are identified and are traced all the way to the thyrothymic ligament to ensure complete resection, and all fatty tissue between the phrenic nerves and all the way down to the diaphragm is included in the resection. This description implies a “T3b” thymectomy according to the MGFA classification.⁴⁹ More or less extensive thymectomies are carried out by some surgeons, but these have largely fallen from favor.

Transcervical Thymectomy

We have reported that noninvasive thymomas less than 4 cm in diameter may be completely resected along with the thymus by a transcervical approach (we would go only as far as 3 cm currently).⁴⁶ However, when using this approach, the surgeon must have a low threshold for conversion to sternotomy if any suggestion of gross invasion is encountered. Strong evidence exists, conversely, that in the absence of thymoma, TCT provides results very similar to more aggressive thymectomy approaches in the treatment of MG.⁵⁰ Table 41-3 lists results of large modern studies of the various approaches to thymectomy for MG. Note that there is no dramatic difference in complete MG remission rates between the proposed approaches to thymectomy.

†Includes only studies representing pure series of extended transcervical thymectomy using the Cooper thymectomy retractor.

‡Values in parentheses represent the most restrictive definition of a complete response.

NA, Data not available.

TCT and transcervical approaches to other masses in the anterior mediastinum are performed through a 5-cm curvilinear incision in the jugular notch. Details of the procedure have been described elsewhere.⁶⁵ In brief, after dissection of the two cervical poles, each is tied with a silk suture and used for traction to aid in dissection of the remainder of the gland. After, or just before, branches from the innominate vein to the gland are ligated and divided, and a Cooper thymectomy retractor (Pilling Co., Fort Washington, PA) is inserted and positioned to maximally lift the sternum as an inflatable bag beneath the shoulders is deflated. Extracapsular removal of the entire gland then proceeds by primarily blunt dissection within the mediastinum by the operator, seated at the head of the table and using a headlight (Fig. 41-4). The resection includes the bulk of the extra-thymic mediastinal fat between the phrenic nerves and down to the diaphragm. The procedure does not remove the pleurae or the fat directly apposed to the pleurae (which are generally removed during sternotomy), tissue posterior to the phrenic nerves, or other areas where ectopic thymic tissue has been described. No drains are left in place. Patients are generally discharged late on the same day of surgery.

Maximal Thymectomy: Trans-sternal and Transcervical

Jaretzki and a few others have for many years advocated “maximal” thymectomy for MG patients, involving a cervical incision in addition to median sternotomy and requiring extensive neck and mediastinal dissection to

FIGURE 41-4 ■ Technique of transcervical thymectomy. The surgeon's view from the head of the table shows the ligated upper thymic poles retracted anteriorly while the branches into the thymus from the innominate vein are controlled. (From Kaiser LR: *Atlas of general thoracic surgery*, St. Louis, 1997, Mosby-Year Book, with permission.)

investigate all areas where aberrant thymic tissue has been described.⁶⁶ Although Jaretzki has argued in favor of this approach, the evidence that this extensive operation provides better control of MG than even the least invasive transcervical approach is controversial (see Table 41-3) and has not convinced many to adopt this procedure.

Thoracoscopic Thymectomy

A number of thoracoscopic approaches to thymectomy have been described that appear to allow complete thymectomy to be performed.^{67,68} Approaches that combine the thoracoscopic and transcervical techniques with sternal lifting have also been reported.⁶⁹ However, there is no doubt that intercostal, thoracoscopic port incisions are more painful than a small incision in the jugular notch as performed for TCT. Thus, there would appear to be little reason to use thoracoscopy in lieu of or in addition to the transcervical approach for nonthymomatous MG unless it can be demonstrated that this allows more complete resection of thymic tissue and results in higher complete responses. This is very unlikely when even “maximal” thymectomy does not result in markedly higher response rates than TCT. Shigemura and colleagues⁷⁰ performed a prospective trial on 20 patients to compare the efficacy of various thoracoscopic approaches with and without an open transcervical approach, and they concluded that a strictly VATS approach resulted in incomplete gland removal.

For smaller, noninvasive thymomas, thoracoscopic approaches have also gained favor. However, concern that inadvertent breaching of the tumor capsule at the time of thoracoscopy would facilitate spread of thymoma by the route that it follows by nature—directly into the pleural space—has led many experienced surgeons to adopt VATS approaches cautiously, if at all. Nevertheless, it has been demonstrated in several series that stage I and II thymomas, generally with a size limit of approximately 4 cm, can likely be safely resected by VATS. One must be concerned, however, that follow-up time is limited in currently published studies, given the known propensity of thymoma to recur even up to 10 years postoperatively.

Robotic Thymectomy

Although conceptually and anatomically little different than a VATS thymectomy, robotic system removal of the thymus can have certain advantages over the VATS approach, and it too is being increasingly applied. Resection of mediastinal masses is probably the ideal intrathoracic application of robotic technology—the robot tends to be the most useful in procedures that require manipulation in smaller, remote spaces where the fully articulating “wrists” provide maximal advantage. In MG, early adopters have presented medium-term experience showing complete stable remission rates at least as good as those reported after VATS thymectomy.^{71,72} For thymoma, although the concern raised just previously for VATS approaches regarding spillage into the pleural space remains relevant, a multicenter European study has

suggested safety and efficacy for stage I-II thymoma.⁷³ Of 79 cases carried out at four centers for tumors with a median 3-cm diameter (mainly from a left-sided approach), one conversion to open surgery was required, no vascular or nerve injuries occurred, and median hospital stay was 3 days. Most importantly, 5-year disease-specific survival was 97%—one patient had diffuse pleural recurrence. A right-sided robotic approach, sometimes with an additional single-port VATS on the left to clearly identify the left phrenic nerve, is advocated by some. Certainly, additional series and longer interval follow-up data will be important as this technology is increasingly applied.

SUMMARY

We have reviewed the various anterior mediastinal masses, paying particular attention to their presentation, diagnosis, and management. The association of thymic disease and MG has been emphasized. Surgical approaches to biopsy and resection of anterior mediastinal masses, including their respective advantages and disadvantages, have been described. The appropriate management of anterior mediastinal masses requires flexibility and versatility on the part of the surgeon with regard to the method selected in each patient for biopsy or resection.

ANATOMY

Using the traditional “three-compartment” classification, the middle mediastinum is bounded anteriorly by the pericardium and posteriorly by the pericardium and membranous wall of the trachea (Fig. 42-1). The lateral borders are composed of the mediastinal pleura, while the superior margin is the thoracic inlet and the inferior margin is the diaphragm. Contained within this space are portions of the airway, the pericardial contents, lymphatics, and nervous structures. The intrathoracic trachea, proximal main-stem bronchi, pericardium, phrenic nerves, heart, ascending aorta, and proximal arch are all located within the middle mediastinum. It also contains a rich network of lymphatic channels and lymph nodes that primarily drain the lungs and esophagus, such as lymph nodes in the paratracheal and subcarinal positions.

The structures located within the middle mediastinum can be the site of neoplastic, inflammatory, degenerative, or infectious pathologic conditions. In addition, the superior aspect of the middle mediastinum is in communication with the inferior aspect of the neck; thus, disorders involving the neck can also involve the mediastinum. Therefore, a thorough understanding of the middle mediastinum and its contents is required of any surgeon who treats conditions that involve the structures located within this space.

DIAGNOSTIC MODALITIES

Signs and Symptoms

Although often asymptomatic, a variety of signs and symptoms may be present in patients with diseases of the

middle mediastinum. Individual presentation depends on the size and location of the lesion and whether it is benign, malignant, inflammatory, or infectious. The most common symptoms include cough, dyspnea, and chest pain. In the presence of malignancy, direct invasion can lead to diaphragmatic paralysis or chylothorax. Compression of the superior vena cava can obstruct blood return from the upper body. Rarely, hormonal or endocrine substrates lead to systemic manifestations, leading to workup and diagnosis of middle mediastinal pathology.

Imaging

The conventional chest radiograph often provides the first indication of an abnormality in the middle mediastinum. Narrowing or deviation of the tracheobronchial tree, enlargement of the pericardial silhouette, and calcification or enlargement of the great vessels are detectable radiographically (Fig. 42-2A). The right paratracheal stripe is formed by the lateral trachea, mediastinal tissue, and paratracheal pleura, and it should be visible on posterior-anterior chest radiograph (CXR). Obliteration of this stripe can indicate the presence of lymphadenopathy in station 4R, a right-sided aortic arch, or a paratracheal mass. Similarly, the aortopulmonary window should appear as a concavity at the interface between the aortic knob and left pulmonary artery on CXR. Fullness in this region is considered abnormal and may reflect lymphadenopathy in the aortopulmonary window. However, because of its limited resolution, CXR often does not provide adequate information about specific mediastinal pathology. Further radiographic assessment by other modalities is necessary for a more accurate assessment.

Computed tomography (CT), often with intravenous or oral contrast, is indicated when mediastinal pathology

FIGURE 42-1 ■ Traditional three-compartment classification of the mediastinum. (Courtesy Gary Chmielewski, MD.)

FIGURE 42-2 ■ **A**, Posteroanterior chest radiograph of a 55-year-old woman with chest heaviness and mild dysphagia to solids. A large middle mediastinal mass is noted. **B**, Computed tomographic scan demonstrates a subcarinal mass. Differential diagnosis includes adenopathy (lymphoma) and bronchogenic or esophageal duplication cyst. Resection revealed a plasmacytoma.

is suspected (see Fig. 42-2B). High-resolution spiral CT, with cross-sectional imaging of structures at intervals as narrow as 1 mm, is the radiologic modality of choice for imaging the middle mediastinum. All structures of the middle mediastinum are visible on CT scan, and their relationship to adjacent structures is often easily delineated. Three-dimensional reconstructions can be created,

and they are particularly useful for detailed assessment of structures, such as the trachea and aortic arch. The presence of calcified mediastinal lymph nodes and pulmonary granulomas may suggest a subacute, benign process, such as mediastinal histoplasmosis.

Magnetic resonance imaging (MRI) may provide additional information in the assessment of middle mediastinal pathology. Advantages of MRI include its ability to differentiate between vascular, solid, and fluid elements in a given mass. MRI has been shown to be superior to CT for assessing tumor invasion into vascular structures.¹ T1-weighted images are preferable for delineating anatomy, whereas T2-weighted images are preferable for characterizing solid from cystic structures.

Positron emission tomography (PET) using fluorine-18 fluorodeoxyglucose (FDG) is a valuable tool for evaluating middle mediastinal pathology. It has become an integral component in the clinical staging of lung and esophageal cancers, as well as in the follow-up of mediastinal lymphomas.^{2,3} The fusion of PET and CT technology increases diagnostic accuracy by allowing precise localization of hypermetabolism.⁴ The degree of FDG uptake is used as a surrogate marker for the degree of metabolic activity in a given tissue. Areas of increased activity are often targeted for biopsy to provide the most high yield results. However, the utility of PET scanning is limited because it is difficult to distinguish between hypermetabolism caused by malignancy and that caused by inflammation. For example, acute mediastinal lymphadenopathy related to pneumonia commonly demonstrates FDG avidity.

Outside of echocardiography, transthoracic ultrasonography is of limited value in the evaluation of the middle mediastinum. However, endobronchial ultrasonography (EBUS) and transesophageal ultrasonography (EUS) have emerged as valuable tools for the evaluation of the mediastinum. Both techniques can be performed using moderate sedation on an outpatient basis. Using EBUS, lymph nodes in stations 2, 4, 7, 10, and 11 can be visualized and sampled. The addition of EUS allows access to lymph nodes in stations 8 and 9. Both modalities can differentiate solid from cystic masses, detect lymph nodes as small as 3 × 5 mm, and allow for reliable ultrasound-guided fine-needle aspiration.⁵

Other modalities, such as leukocyte scintigraphy, lymphoscintigraphy, and metaiodobenzylguanidine (MIBG) scanning, have limited and very specific indications in the evaluation of pathology in the middle mediastinum.

Invasive Techniques

CT-Guided Percutaneous Biopsy

Tissue from masses in the middle mediastinum can be obtained with CT-guided percutaneous biopsy. Both fine-needle biopsy and core needle biopsy can be performed using CT guidance. This technique offers the advantage of obtaining tissue for diagnosis using only local anesthesia on an outpatient basis. Success rates, particularly with core needle biopsy, are excellent in experienced hands. The disadvantage of these techniques is the possibility of obtaining an inadequate amount of

tissue for diagnosis or failure to make a diagnosis in relatively small masses.

Endoscopic Ultrasound and Endobronchial Ultrasound-Guided Biopsy

EBUS and EUS are being used with increasing frequency to obtain tissue from the mediastinum. With EUS, both fine-needle and core biopsy specimens may be obtained with minimal morbidity. EBUS-guided fine-needle aspiration can be used to obtain tissue from masses located near the trachea and mainstem bronchi. These modalities are increasingly used in the staging of lung cancer, but can also be used to obtain tissue from other middle mediastinal masses. Pathologic lymph nodes are often homogeneous, hypoechoic, round, and larger than 1 cm in diameter. Several studies have suggested that combining EBUS- and EUS-guided biopsy has a higher accuracy than either procedure alone and has a diagnostic accuracy comparable to mediastinoscopy in the staging of patients with suspected lung cancer.⁶⁻¹⁰ Additional benefits of endoscopic ultrasound-guided biopsy are that it carries a low morbidity profile, usually does not require a general anesthetic, is preferred by patients,¹¹ and is cost-effective¹² compared with surgical staging.

Cervical Mediastinoscopy and Anterior Mediastinotomy

Cervical mediastinoscopy has been traditionally considered the gold standard for evaluation of mediastinal pathology. In experienced hands, the procedure can be performed with less than 2% morbidity and less than 0.1% mortality. It offers the advantage of obtaining a large amount of tissue from mediastinal lymph nodes in the pretracheal, paratracheal, and subcarinal regions, but the surgeon cannot access the inferior or posterior mediastinum or the aortopulmonary window.

On occasion, a 3- to 4-cm parasternal anterior mediastinotomy (Chamberlain procedure) may be necessary to obtain tissue for diagnosis. Under direct visualization, anterior mediastinal masses, aortopulmonary window lymph nodes, and para-aortic masses can be accessed for sampling. The primary disadvantages of cervical mediastinoscopy and anterior mediastinotomy are that they require an incision and general anesthesia. However, with either technique, a histologic diagnosis can be obtained in a majority of cases.

Video-Assisted Thoracoscopic Surgery

The use of video-assisted thoracoscopic surgery (VATS) in the diagnosis and management of thoracic conditions has gained widespread acceptance. VATS allows the surgeon to visualize the entire pleural space and ipsilateral mediastinum. Using VATS and dedicated instruments, tissue can be obtained from nearly all mediastinal compartments. In addition, many middle mediastinal masses can be managed effectively with VATS techniques. A VATS approach is particularly useful in the evaluation and treatment of lesions that require direct visualization, such as those in close proximity to the heart and great

vessels. The principal disadvantages of VATS are that it requires general anesthesia and split-lung ventilation, and the surgeon risks seeding the pleural space if a malignant tumor is disrupted during dissection. However, VATS has emerged as a powerful tool in the armamentarium of the thoracic surgeon.¹³

Other Techniques

Rarely, other attempts fail, or the preceding procedures cannot be used in a specific instance. Then, a thoracotomy or sternotomy may be necessary to obtain tissue to establish a histologic diagnosis of a middle mediastinal mass.

DISEASES OF THE MIDDLE MEDIASTINUM

Mediastinal Lymphadenopathy

Enlargement of middle mediastinal lymph nodes is seen in a wide variety of disorders. Metastasis from lung cancer is the most common cause of malignant mediastinal lymphadenopathy. Lymph nodes located in the paratracheal region, tracheobronchial angle, and subcarinal space are often involved. When infiltrated by malignancy, these lymph nodes can appear enlarged on imaging studies or demonstrate hypermetabolism on PET scan. Esophageal and tracheal malignancies, mesothelioma, and extrathoracic tumors with metastases to the lungs can subsequently spread to mediastinal lymph nodes. Extrathoracic malignancies can also metastasize directly to mediastinal lymph nodes, without the development of pulmonary metastases. The middle mediastinum may be the primary site of disease in Hodgkin lymphoma and primary mediastinal B cell lymphoma. Typically, however, mediastinal lymphomas occur with anterior mediastinal masses. Lymphangiomas are another rare cause of middle mediastinal lymphadenopathy.

Among the benign disorders that manifest with middle mediastinal lymphadenopathy, inflammatory and infectious causes predominate (Table 42-1). Sarcoidosis is one of the most common causes of benign mediastinal lymphadenopathy. Most commonly, this is seen on CT scan as hilar or as mediastinal lymphadenopathy. Sarcoidosis can create a confusing picture in the setting of a known malignancy. Histologic confirmation demonstrating non-necrotizing granulomas and elevated levels of angiotensin-converting enzyme are required for diagnosis. Although PET scan cannot make a diagnosis of sarcoidosis, some authors have reported using FDG uptake as a marker for response to therapy.¹⁴

Histoplasmosis is a common cause of mediastinal lymphadenopathy, particularly in the Mississippi, Ohio, and Missouri River valleys. This fungal infection has a spectrum of disease manifestations in the thoracic cavity, including benign lymphadenopathy (with characteristic calcification), broncholithiasis, granuloma formation, and mediastinal fibrosis. Other fungal infections that might be seen in specific regions include cryptococcosis and coccidioidomycosis. Mycobacterial infections, both

tuberculous and nontuberculous, may present with hilar and mediastinal lymphadenopathy as well. As in malignant disease, involvement of mediastinal lymph nodes can occur secondary to a primarily parenchymal process, such as bacterial or viral pneumonia.

Other rare causes of middle mediastinal lymphadenopathy include congestive heart failure, which can lead to engorgement of lymph nodes in the mediastinum. Giant lymph node hyperplasia, or Castleman disease, commonly manifests as a solitary lesion but may have a multicentric appearance. Although this disease can be found anywhere, the majority (70%) of cases originate in the thorax.¹⁵ The etiology of giant lymph node hyperplasia is unknown, and patients are typically asymptomatic.

Tracheal Disorders

The trachea is a tubular structure that connects the larynx with the mainstem bronchi. In the average adult, it measures 11 to 13 cm in length. The trachea begins at the cricoid, the only circumferential cartilaginous ring, and ends at the bifurcation into the right and left mainstem bronchi. The intrathoracic portion of the trachea and both mainstem bronchi course through the middle mediastinum and may be involved in a variety of disorders. Primary tumors of the trachea, such as squamous cell carcinoma and adenoid cystic carcinoma, can involve any portion of the airway, but they are usually seen in the intrathoracic portions. Other diseases, such as amyloidosis and Wegener granulomatosis, can also involve the trachea. Tracheomalacia, which may be congenital or secondary to other disorders, such as chronic obstructive pulmonary disease, can involve the intrathoracic trachea as well as the mainstem bronchi.

Bronchogenic cysts are the most common congenital foregut cysts, resulting from abnormal budding of the tracheolaryngeal groove.¹⁶ Unlike esophageal duplication cysts, there is no association with congenital spinal and skeletal abnormalities. Approximately 80% of bronchogenic cysts are located in the middle mediastinum, most commonly in close proximity to the carina and right mainstem bronchus. Bronchogenic cysts are lined with ciliated, columnar respiratory epithelium or cuboid epithelium containing mucous glands. Mucous production typically leads to gradual cyst enlargement over

time. The presence of an air-fluid level suggests a communication with the airway. These cysts may be incidentally found, or patients may exhibit symptoms such as cough, dyspnea, or dysphagia owing to compression from the cyst. The risk of infection is great enough that routine resection is recommended in those who will tolerate surgery. This can usually be performed in a minimally invasive fashion; however, if a cyst is actively infected, surgery should be delayed until a course of antibiotics is administered.

Pericardial Disorders

The pericardial sac serves multiple purposes, including mechanical protection of the heart and lubrication of cardiac movement. It also has an influence on the mechanical properties of cardiac function. The most common condition affecting the pericardium is an effusion. The presence of a pericardial effusion can lead to compromised diastolic filling. The most common cause of pericardial effusion is malignancy, which accounts for more than 75% of cases, with lung and breast cancer predominating.¹⁷ Other causes of pericardial effusion include myocardial infarction, cardiac surgery, and trauma. Treatment, when indicated, involves drainage by either pericardiocentesis or the creation of a pericardial window.

Acute pericarditis can be caused by a wide variety of disorders, including connective tissue disorders, uremia, infection, malignancy, and cardiac surgery. However, most cases are considered idiopathic because of the inability to identify a clear etiology. Patients typically present with fevers, malaise, chest pain, and leukocytosis. The pleuritic chest pain is often increased with deep inspiration, and a friction rub may be heard on physical examination. Electrocardiography may reveal diffuse PR depression and ST segment elevations, without Q waves or T wave inversions. CXR may demonstrate cardiomegaly, reflecting a pericardial effusion. Echocardiogram is indicated to assess the volume of pericardial fluid and to rule out other pathology, such as an intrapericardial neoplasm. Treatment generally consists of management of the underlying condition, nonsteroidal anti-inflammatory medication, colchicine, with or without steroids.¹⁸ When pericarditis is severe or recurrent, the condition can progress to a chronically diseased pericardium that constricts cardiac function by impairing diastolic filling. Constrictive pericarditis must be differentiated from restrictive cardiomyopathy, and it may require surgical resection of the pericardium for cure.

Pericardial cysts occur in approximately 1 in 100,000 persons, and they are thought to arise during embryonic development. They are most commonly found in the right cardiophrenic angle. Pericardial cysts are usually asymptomatic; however, approximately 20% of patients will present with shortness of breath, cardiac compression, or infection. They are often first identified on routine CXR. CT scan and echocardiography can help to differentiate pericardial cysts from foramen of Morgagni hernias or other mediastinal pathology. Treatment consists of percutaneous drainage or surgical resection.

Pericardial neoplasms are rare—mesothelioma is the most common primary pericardial neoplasm. Metastatic neoplasms to the pericardium (e.g., from lung, breast, prostate, and lymphoma) are far more common than primary tumors.

Mediastinal Infections

Acute mediastinal infection is relatively rare. Most instances result from processes that involve the mediastinum secondarily, such as esophageal perforation, sternal infections after sternotomy, and tonsillar or odontogenic abscess. The most common cause of esophageal perforation is iatrogenic, occurring during endoscopic procedures in the cervical esophagus. However, spontaneous perforation or iatrogenic injury during intrathoracic procedures may occur. Esophageal perforation leads to contamination of the middle mediastinum by oropharyngeal secretions, which results in a spectrum of clinical presentations such as abscess formation or sepsis syndrome secondary to mediastinitis. Treatment depends on the location of the perforation, the timing of presentation, and the clinical condition of the patient. General principles of treatment include wide drainage, débridement of necrotic tissue, and closure of the perforation, either primarily or with endoluminal stenting.

Infections after sternotomy can contaminate the middle mediastinum with skin flora. Most commonly, such infections occur after cardiac surgical procedures. Risk factors include diabetes mellitus, redo sternotomy, and harvesting of bilateral internal mammary arteries. Treatment includes antibiotics, removal of any foreign material, prompt surgical débridement of devitalized tissue and bone, and possible muscle flap coverage.

Acute necrotizing mediastinitis is a life-threatening condition that occurs when oropharyngeal bacterial flora gain access to the middle mediastinum by following the perivascular, pretracheal, or retrovisceral planes. It is most commonly seen in men in their fourth decade of life. Necrotizing mediastinitis typically occurs secondary to odontogenic abscesses, and it is the result of a polymicrobial mix of aerobes and anaerobes. CT scan of the neck and chest is key in determining the extent of mediastinal involvement. Treatment generally consists of broad-spectrum antibiotics and early surgical drainage through the neck, chest, or both. Complete débridement is paramount for survival, and a surgeon's threshold to perform a transthoracic drainage in addition to cervical drainage should be low. The underlying cause must be treated promptly.

Fibrosing mediastinitis is a rare disorder characterized by the proliferation of acellular collagen and fibrous tissue within the mediastinum. This proliferation is thought to be caused by an immune-mediated hypersensitivity response to *Histoplasma capsulatum* infection.¹⁹ There are two forms: focal and diffuse. In its most severe form, the fibrotic process encases mediastinal structures including the airway, superior vena cava, and pulmonary arterial and venous branches, leading to compression of these structures with resultant symptoms. Antifungal

therapies generally provide little benefit, and treatment, when necessary, centers on relief of symptoms. Surgical and nonsurgical vascular interventions often provide some symptomatic relief; however, the benefit is often of limited duration.²⁰

Neuroenteric Cysts

Other Masses of the Posterior Mediastinum

INFECTIONS OF THE MEDIASTINUM

SUMMARY

The posterior mediastinum is an anatomically diverse region that includes visceral organs, major vascular structures, large neural structures, and important lymphatic vessels. Lesions that originate in the mediastinum are relatively rare compared with the diverse pathology that can involve the mediastinum secondarily, although metastatic disease appearing in the posterior mediastinum, excluding the spine, is unusual. The most common lesions arising within the posterior mediastinum are primarily tumors of neurogenic origin. Less common is a potpourri of lesions including vascular tumors, mesenchymal tumors, and lymphatic lesions.

ANATOMY

The posterior mediastinum, also called the *paravertebral compartment*, is a defined space between the posterior pericardium and the anterior spinal ligament including the paravertebral gutters. According to the traditional four-compartment model, the mediastinum is divided into anterior, middle, posterior, and superior compartments. The posterior mediastinum is bounded superiorly by the inferior border of the T4 vertebral body.^{1,2}

In the traditional three-compartment model without a superior division, the entire length of the spine is included in the posterior mediastinum.² The diaphragm is the common inferior border for all three compartments. Within these boundaries, the posterior mediastinum contains the esophagus, descending aorta, sympathetic chain and vagus nerves, thoracic duct, azygos and hemiazygos veins, fat, and lymph nodes (Fig. 43-1).¹ Recently, Fujimoto and colleagues³ proposed a new mediastinal compartment classification based on transverse axial computed tomographic (CT) imaging. Because of the routine use of CT scanning in the diagnosis and

management of these lesions this classification appears to be more user-friendly and clinically applicable. The authors proposed the division of the mediastinum into four compartments that are visible on CT axial images: superior portion, anterior mediastinum (prevascular zone), middle mediastinum (peri-tracheoesophageal zone), and posterior mediastinum (paravertebral zone). The authors validated their classification by retrospectively analyzing 445 pathologically proven mediastinal tumors (Fig. 43-2).

EPIDEMIOLOGY

Significant differences exist between children and adults with respect to the location of mediastinal masses.⁴ In adults, 65% of the lesions arise in the anterosuperior, 10% in the middle, and 25% in the posterior compartments; this distribution is reversed in children, in whom 25% of lesions arise in the anterosuperior, 10% in the middle, and 65% in the posterior compartments. In general, the incidence of posterior mediastinal lesions is higher in children, whereas anterior lesions predominate in adults.

DIAGNOSIS

Approximately 50% of posterior mediastinal lesions are asymptomatic and are detected on chest radiographs or CT scans taken for unrelated reasons. As a rough guideline, the absence of symptoms is more commonly associated with a lesion that likely is benign, whereas the presence of symptoms suggests malignancy. The percentage of patients with symptoms arising from a mediastinal mass precisely parallels or equals the incidence of

FIGURE 43-1 ■ Lateral chest film divided into three anatomic subdivisions with the most common location of the tumors and cysts. (From Davis RD Jr, Sabiston DC Jr: Primary mediastinal cysts and neoplasms. In Sabiston DC Jr, editor: *Essentials of surgery*, Philadelphia, 1987, WB Saunders.)

malignant lesions. In adults, 50% to 60% of lesions are symptomatic, whereas the percentage of symptomatic lesions is higher in children, ranging from 60% to 80%. Because the incidence of symptoms parallels the incidence of malignant lesions, a child with a mediastinal mass is considerably more likely to have a malignant neoplasm than is an adult with a mediastinal mass. When a posterior mediastinal mass is discovered, a detailed history and physical examination should be obtained, looking particularly for signs such as hoarseness or Horner syndrome. The age of the patient also significantly narrows the diagnostic possibilities.

Computed tomography (CT) is the imaging modality of choice for the posterior mediastinum because of its ability to visualize a mass on an axial cut and to provide some idea as to the extent of invasion, although distinguishing abutment from invasion remains difficult. CT often can distinguish among the various lesions and identify the origin, allowing a correct diagnosis often based strictly on radiographic imaging.⁵ Magnetic resonance imaging (MRI) has been useful in certain circumstances, specifically with dumbbell tumors to assess the presence and extent of invasion within the spinal canal, but also for cysts, and extramedullary hematopoiesis. CT scanning, however, remains the better imaging modality for most posterior mediastinal masses.⁶ Mediastinal sonography, although less expensive and comparable to CT in

the diagnosis of many mediastinal masses, is not useful in the posterior mediastinum.⁷

The decision to sample a mediastinal mass is not straightforward. Obtaining a biopsy before proceeding with resection is not necessary in some cases and potentially harmful in others. The likelihood of a positive finding in a biopsy specimen depends on the presence of local symptoms in addition to the location and extent of the lesion. Lesions in the posterior mediastinum require either fine-needle aspiration (CT guided) or a thoracoscopic approach.^{8,9} If these procedures are not possible because of location in the paravertebral gutters, a limited posterolateral thoracotomy should be used to obtain adequate tissue for diagnosis or, alternatively, simply to resect the lesion in its entirety.^{10,11}

SURGICAL APPROACHES TO THE POSTERIOR MEDIASTINUM

Multiple standard approaches have been described to access the posterior mediastinum depending upon the location relative to the particular aspect of the spine. These include an anterior transcervical approach, a posterior paravertebral approach, posterolateral thoracotomy or video-assisted thoracoscopy¹³ or via a transabdominal incision (Fig. 43-3).

The transcervical approach is accomplished through an incision along the anterior border of the sternocleidomastoid muscle. The region that is most difficult to access is at the level of the T1 vertebral body, because transthoracic and transcervical approaches are not ideal. For a lesion at this location, an extension of the incision along the anterior border of the sternocleidomastoid muscles down to the manubrium and then out along the infraclavicular region allows the manubrium to be divided and retracted upward, giving access to the region of the T1 vertebral body. We have used this approach for a number of lesions with great success. Di Rienzo and colleagues¹² have described a modified transmanubrial osteomuscular sparing approach for resection of lesions between C7 and T2, recognizing that either a right-sided or left-sided approach can be used because the vascular dissection is similar on both sides.¹²

When more inferior posterior mediastinal masses need to be accessed, the paravertebral approach can be used by resecting posterior segments of one or more ribs and entering the retropleural plane that leads to the posterior mediastinum. Standard posterolateral thoracotomy, the most commonly used approach, provides excellent access to the posterior mediastinum; the location of the lesion determines the intercostal space to be entered.

The posterior mediastinum can also be accessed transabdominally through the esophageal hiatus, important in various antireflux procedures or hiatal hernia repairs, and for mobilization of the mediastinal esophagus when performing a transhiatal esophagectomy.¹³ A combined cervical approach with transabdominal mobilization allows for the removal of the esophagus extrapleurally ideally without entering either the right or left pleural reflection. A transabdominal approach at the level of the hiatus also

allows access to the cisterna chyli, which may need to be ligated when dealing with a chylothorax when ligation of the thoracic duct in the chest has been unsuccessful.

Currently it is the preference of most surgeons to access lesions of the posterior mediastinum using a video-assisted thoracic surgical (VATS) approach,¹³ but this depends on the surgeon's experience and comfort with video-assisted procedures. If the intent is strictly to secure material for histologic study, then VATS clearly should be the procedure of choice.^{9,14,15} Zierold and Halow¹⁶ conducted a retrospective review that described the use of a VATS approach for posterior mediastinal neurogenic lesions. Twenty-nine patients (13 men, 16 women; 26 to 68 years old) who underwent a thoracoscopic resection were identified. Preoperative imaging included chest radiography and CT in all patients and MRI in 15 of 29 patients (52%). All tumors were located in the posterior mediastinum and in none was there preoperative evidence of invasion or malignancy. Conversion to an open procedure was required in 12 of 29 (41%) patients (minithoracotomy in 11, posterolateral thoracotomy in 1). Tumor size necessitating conversion to an open procedure (mean = 4.79 cm) and tumor size amenable to thoracoscopy alone (mean = 3.84 cm) were not significantly different ($P < 0.09$). They concluded that thoracoscopic resection could be performed successfully, regardless of tumor type or size; however, malignant lesions, local invasion, and tumors larger than 5 cm may require an open procedure. Cardillo and associates¹⁷ detailed their experience with 93 patients who underwent resection of a posterior mediastinal neurogenic tumor. The tumor was resected with a videothoracoscopic approach in 57

patients; 44 underwent VATS only, and 13 required conversion to an open approach. Mean operative time was significantly shorter in the VATS group, as was the median postoperative hospital stay and postoperative pain. No recurrences were noted at a mean follow-up of 73 months.

More recently, robotic surgery has been used for the resection of mediastinal lesions, including those in the posterior mediastinum. Melfi and colleagues¹⁸ recently reported on a 10-year experience of mediastinal robotic surgery in a single referral center. Sixty-nine patients were resected using the da Vinci robotic system, including 13 paravertebral neurogenic tumors. Patients were positioned in the lateral decubitus position, and the robotic arms were located based on the site of the lesion generally at the fourth intercostal space. Lesions were removed through the anterior port, where the intercostal space is widest, and the largest incision used was 3 cm. No additional utility incision was performed. The authors noted significant progression on the learning curve, especially related to the resection of anterior mediastinal lesions where the mean operative time between the first 10 resections and the second 10 decreased significantly from a mean of 194 minutes to 97.5 minutes. The authors confirmed the safety and feasibility of the robotic approach for different mediastinal lesions, but they point out that cost may be an important limitation.

LESIONS OF THE MEDIASTINUM

Neurogenic Tumors

Neurogenic tumors of the thorax commonly occur in the posterior mediastinum and primarily affect young adults and children.¹⁹ In recent decades, although these tumors continue to be the most common malignant neoplasm in children, they have become less common than tumors of the anterior mediastinum (thymomas or lymphomas) in adults. Neurogenic tumors currently represent approximately 15% of all mediastinal masses in adults. Furthermore, in adults the malignancy rate of neurogenic tumors is less than 10%. In children, 50% of these lesions are malignant.¹⁹ Takeda and colleagues reviewed their experience with 146 patients with intrathoracic neurogenic tumors treated during a 50-year period. In this series of 60 pediatric and 86 adult patients, there were 51 gangliogliomas, 37 schwannomas, 30 neurofibromas, 18 neuroblastomas, 5 ganglioblastomas, and 5 lesions classified as "other."²⁰ Of these lesions, 136 were located in the posterior mediastinum, but only 13 patients (8.9%) had extension of tumor into the spinal canal; 84% of adults and 60% of children were asymptomatic at the time of presentation, and 20.5% of the lesions were malignant, with these occurring predominantly in the first 5 years of life.

Neurogenic tumors originate from embryonic neural crest cells located near the spinal ganglia and from either sympathetic or parasympathetic components (Box 43-1). The differential diagnosis for neurogenic tumors arising from intercostal nerves includes neurofibroma, neurilemmoma, and neurogenic sarcoma. Tumors arising from

sympathetic ganglia include ganglioneuroma, ganglioneuroblastoma, and neuroblastoma. Pheochromocytomas arising from paraganglion cells also may be seen in the posterior mediastinum. Neurogenic tumors rarely arise from the phrenic or vagus nerves.

Neurogenic tumors may be benign or malignant, with benign lesions classified as either neurilemoma (schwannoma) or neurofibroma. Neurilemmas are more common than neurofibromas. Of patients presenting with nerve sheath tumors, 25% to 40% have neurofibromatosis type 1 (NF1; von Recklinghausen disease), an autosomal dominant disorder caused by mutation in the neurofibromin gene found on chromosome 17q11.2. The worldwide incidence of NF1 is 1 in 2500 to 1 in 3000 individuals. Malignant tumors (neurogenic sarcomas or malignant schwannomas) are unusual with the incidence of malignancy greater in tumors found in patients with NF1 (10% to 20%).

Patients with benign lesions most often are asymptomatic as opposed to patients with malignant tumors, who frequently manifest symptoms of spinal cord compression or have cough, dyspnea, chest wall pain, or hoarseness. Horner's syndrome caused by involvement of the superior cervical ganglion of the sympathetic chain is an unusual, but not unheard of, presenting sign. Because most patients with neurogenic tumors are asymptomatic, the initial diagnosis usually is made on the basis of findings noted on a chest radiograph or CT scan performed for a different reason. Rarely, a patient might have a pheochromocytoma or a chemically active neuroblastoma or ganglioneuroma. In all symptomatic patients, especially those with a history of significant hypertension or hypermetabolism, serum catecholamine levels and 24-hour urine levels of homovanillic acid and vanillylmandelic acid should be obtained. If these levels are elevated, suggesting pheochromocytoma, preoperative α -adrenergic blockade along with a β -blocker need to be administered to avoid intraoperative complications owing to episodic catecholamine release during tumor manipulation.

Neurogenic tumors that arise from intercostal nerves typically prove to be neurilemmas or neurofibromas.²¹ Neurilemmas (schwannomas) are the most common neurogenic tumors.^{22,23} On histologic examination, they appear as well-encapsulated, firm, gray-tan masses.²⁴

They tend to occur in one of two morphologic patterns: either with an organized architecture with a cellular palisading pattern of growth (Antoni type A) or a loose reticular pattern (Antoni type B²⁵; Fig. 43-4). Neurofibromas are poorly encapsulated, with a random arrangement of spindle-shaped cells.²⁶ Associated with neurofibromatosis type 1, these tumors tend to form in the paravertebral gutters and have the potential to degenerate into neurosarcoma, a major indication for their surgical excision.

Neuroblastoma, ganglioneuroblastoma, and ganglioneuroma are tumors of the sympathetic nervous system that arise from primitive sympathetic ganglia and are referred to collectively as *neuroblastic tumors*.²⁷ These tumors can arise from wherever sympathetic nerves exist, and they are seen in the neck, posterior mediastinum, adrenal gland, retroperitoneum, and pelvis. The three tumors differ in their degree of cellular and extracellular maturation and represent a continuum of maturation and differentiation. Immature, highly malignant tumors tend to be aggressive and occur in younger patients (median age, just under 2 years), whereas mature tumors, specifically ganglioneuromas, occur in older children (median age, approximately 7 years) and tend to behave in a benign fashion.²⁷

Ganglioneuromas usually manifest as a benign tumor composed of ganglion cells and nerve fibers. These are the most common neurogenic tumors in children and usually appear at an early age located in the paravertebral region; most commonly, they are an incidental finding on a routine chest radiograph. These tumors are fully differentiated and appear as well-encapsulated lesions on cross-sectional imaging and often exhibit areas of cystic degeneration. Surgical resection is the definitive treatment for these lesions and is curative (Fig. 43-5).

Ganglioneuroblastomas are composed of both mature and immature ganglion cells and have intermediate malignant potential somewhere between ganglioneuromas and neuroblastoma.²⁸ These malignant tumors possess a recognizable capsule and most commonly manifest with symptoms. Of the two categories of ganglioneuroblastoma, the composite type presents with evidence of metastatic disease in 65% to 70% of patients while in the so-called diffuse type fewer than 5% of patients develop metastatic disease.

Neuroblastomas are highly malignant tumors that occur in young children and infants. The majority of these tumors, more than 75% of them, occur in children younger than 4 years of age. These tumors account for greater than 50% of the neurogenic tumors of the mediastinum in children, although intrathoracic lesions account for only approximately 20% of neuroblastomas. On histologic examination, these tumors are composed of small, round immature cells organized in a rosette pattern. The tumors are highly invasive, and by the time the diagnosis is made, they have often metastasized to the regional lymph nodes, bone, brain, liver, and lung. Interestingly, in certain patients, they have a relatively benign course, even when metastatic. Symptoms at the time of diagnosis typically include cough, fever, dysphagia, chest pain, and occasionally paraplegia. At times, the patient may have paraneoplastic syndromes such as profuse

FIGURE 43-4 ■ **A**, Schwannoma presenting at the T1-T2 level as seen on **(A)** coronal CT image. **B**, Note the proximity to the vertebral body also well seen on the axial image. **C**, The relationship between the lesion and the lung parenchyma is well demonstrated.

watery diarrhea secondary to vasoactive intestinal protein syndrome, opsoclonus-polymyoclonus syndrome, and pheochromocytoma-like syndrome. Features such as DNA content, the presence of tumor proto-oncogenes, and catecholamine synthesis correlate with prognosis, and their presence or absence aids in stratifying patients as high, intermediate, or low risk. Ganglioneuroblastomas and neuroblastomas are staged from stage I, a well-circumscribed noninvasive tumor to stage IV-S, where disseminated disease is present. Treatment consists of a multimodality approach including surgical debulking, systemic chemotherapy, and radiation therapy. Overall 5-year survival rate for neuroblastoma is slightly greater than 20%. Despite recent advances in treatment, including bone marrow transplantation, neuroblastoma in most patients remains a relatively lethal tumor, accounting for

10% of pediatric cancers but 15% of cancer deaths in children.²⁹ Because of the rarity of these lesions children with these tumors should be, and usually are, managed in specialized centers with most being entered on cooperative group treatment protocols.

A CT scan can help to elucidate the tumor type and extent of tumor involvement (Fig. 43-6).^{6,27} Neurogenic tumors from peripheral nerves appear as well-defined, round or oval masses in the paravertebral gutter that are noncalcified. Neurilemmomas have variable enhancement with either homogeneity or heterogeneity.³⁰ With enhanced CT, these tumors demonstrate variable attenuation, depending on their histology. Neurofibromas are usually homogeneous, low-attenuation lesions when visualized on unenhanced CT. Enhanced CT demonstrates homogeneous enhancement or early central

FIGURE 43-5 ■ **A**, Axial CT image demonstrating a ganglioneuroma. **B**, The same lesion as seen on MRI. **C**, Intraoperative photograph of a ganglioneuroma as seen through the thoracoscope. (Courtesy Dr. John Kucharczuk.)

blush. Malignant nerve sheath tumors show variable attenuation.²³

Tumors arising from the sympathetic chain expand along the spinal axis, making them difficult to detect on a lateral view. Sympathetic chain tumors do not demonstrate calcification or bone changes. Characteristic radiographic findings of ganglioneuromas include oblong, homogeneous low-attenuation lesions on both enhanced and unenhanced CT. Neuroblastomas appear as aggressive soft tissue lesions commonly with

calcification. Ganglioneuroblastomas appear with combined radiographic features of both ganglioneuromas and neuroblastomas. On CT scans, paragangliomas characteristically appear in the aortopulmonary window with significant enhancement following administration of contrast medium.²⁵ MRI is useful in further delineating the relationship of neurogenic tumors to adjacent structures such as the spinal cord, aorta, and esophagus, although differentiating between abutment and invasion remains difficult.

FIGURE 43-6 ■ CT scan of a schwannoma showing the proximity to the vertebral body and the trachea seen on both the mediastinal window (A) and parenchymal window (B). (Courtesy Dr. John Kucharczuk.)

Tumors located in the posterior mediastinum that extend into the spinal canal through the intervertebral foramen are referred to as *dumbbell tumors*. Preoperative determination of intraspinal involvement of a neurogenic tumor is critical as surgical intervention mandates a combined thoracic surgical-neurosurgical procedure to avoid bleeding within the spinal canal that could lead to spinal cord compression.³¹⁻³⁴ This can be addressed by obtaining an MRI study looking for tumor within the spinal canal. These patients rarely exhibit symptoms of spinal cord compression. Approximately 10% of patients with neurogenic tumors have extension through a vertebral foramen. Although most of these lesions are benign, approximately 1% to 2% are malignant. MRI typically shows a smoothly rounded, homogeneous density abutting the vertebral column.

If a decision is made to obtain tissue, percutaneous fine-needle aspiration biopsy is an appropriate modality to confirm a diagnosis of a neurogenic tumor. A biopsy specimen that reveals a spindle cell

neoplasm with characteristic radiographic findings is diagnostic of a neurogenic tumor. Biopsy specimens that demonstrate a combination of spindle cells and ganglion cells are diagnostic of ganglioneuromas. Immunohistochemical analysis can clinch the diagnosis, particularly with molecular markers such as S-100 tumor antigen.^{35,36}

Surgical intervention is the standard of care for neurogenic tumors; thus, biopsy should be performed only if the results will alter therapy. Traditionally, surgical resection of a posterior mediastinal neurogenic tumor was accomplished through a posterolateral thoracotomy, and this remains an excellent and safe approach. Recent improvements in video-assisted thoracoscopic surgery have allowed minimally invasive approaches to diagnosis and treatment of many tumors in the posterior mediastinum.³⁷ Advantages of thoracoscopic surgery compared with the classic thoracotomy operation include decreased operative time, decreased average length of postoperative hospitalization, and in many patients less postoperative pain.³⁸ Benign intrathoracic tumors are ideal lesions for resection by a video-assisted technique.

Thoracoscopic resection of posterior mediastinal neurogenic tumors can be performed successfully regardless of tumor type or size. However, malignant transformation, local invasion, and tumors larger than 5 cm are characteristics that increase the likelihood of requiring conversion to an open procedure.¹⁶

The standard surgical approach involves a posterolateral thoracotomy incision and exposure of the posterior mediastinum (Fig. 43-7). The tumor is always found in a paravertebral location, and the resection is begun first by incising the overlying pleura and then, with a combination of sharp and blunt dissection, removal of the lesion from the underlying vertebral bodies. Rarely is there any invasion of the bony vertebral body, but it is important to recognize any involvement of a neural foramen. If, in dissecting at the origin of the involved nerve root, it appears that the neural foramen is widened, this may indicate that the tumor is present within the spinal canal. If the foramen is widened, it is best to have a neurosurgeon perform a foraminotomy to ensure complete excision of the lesion and to ensure that tumor is either not left in the canal or divided, causing bleeding within the canal. The involved nerve root itself is routinely taken as part of the resection, although at times a portion of the root may be spared as long as the tumor is completely resected. Some of these tumors arise from the sympathetic chain, and it is important to recognize this and to resect that portion of the sympathetic chain. Care should be taken to avoid resection of segmental vessels, if possible.

Once the pleura has been incised, it usually is straightforward to mobilize these lesions with a combination of sharp and blunt dissection. Complete resection can be accomplished in essentially all cases. The procedure often starts with videothoracoscopic visualization of the tumor and mobilization with the tumor removed through a small incision in the skin. However, if mobilization proves difficult by the videothoracoscopic approach, there should be no hesitation about converting to an open procedure. This is especially important with lesions at the thoracic inlet.

FIGURE 43-7 ■ **A**, Posteroanterior (PA) and lateral chest radiograph of a 17-year-old girl with wheezing and chest discomfort. Note the paraspinal mass seen on the PA view with confirmation of the posterior location on the lateral film. **B**, CT scan confirming the presence of a mass in the posterior mediastinum located along the vertebral body. Note the proximity to the aorta. The mass extended from the T3 level to T8. **C**, Sagittal MRI showing the paraspinal location of the mass and confirming the absence of invasion into the spinal canal. **D**, Intraoperative view of the mass at the time of thoracotomy. **E**, The intact specimen along with the appearance of the inside of the mass after sectioning. Final pathologic analysis revealed a ganglioneuroma.

When it is known that there is tumor involvement within the spinal canal, a well-described approach is the one-stage removal of the tumor performed through a posterolateral thoracotomy combined with transthoracic partial laminectomy.³⁹ This surgical approach avoids two incisions and limits traction on the spinal cord.⁴⁰

Alternatively, an initial posterior approach to the spine with laminectomy and removal of that portion of tumor within the canal is immediately followed by thoracotomy with resection of the intrathoracic paravertebral tumor.

A more recently described procedure avoids a thoracotomy and invasion of the parietal pleura and uses a

dorsal approach to perform a laminectomy with resection of a small portion of the neighboring rib head and neck.⁴¹ In either case, once a dumbbell tumor has been recognized, a combined two-team approach with thoracic surgeons and neurosurgeons working together to perform a one-stage removal is the procedure of choice.^{34,42}

The prognosis of primary neurogenic mediastinal tumors varies with their histopathology. Patients with benign neurogenic tumors have an excellent prognosis with complete surgical excision; patients with malignant neurogenic tumors still have poor long-term survival prospects.¹⁹ Recurrence of a benign lesion is unusual.⁴³ Kang and colleagues⁴⁴ reviewed the results of surgical treatment of 38 children with malignant mediastinal neurogenic tumors seen during an 18-year period. There were 23 (60.5%) neuroblastomas, 14 (36.8%) ganglioneuroblastomas, and 1 malignant neuroepithelioma. The mean age for the series was 3.4 ± 3.0 years, and 26 of the patients were symptomatic at presentation. Complete gross resection was possible in 30 patients, with 5-year survival of 95.2% for localized tumors and 52.5% for stage IV tumors.

Spontaneous regression of neuroblastomas, though rare, has been reported. Stage I (noninvasive) neuroblastomas are managed by resection alone, whereas stage II lesions (locally invasive on same side of midline) require postoperative irradiation. Stage III lesions (invasive across the midline) and stage IV lesions (systemic metastasis) require multimodality treatment including debulking, radiation therapy, chemotherapy, and a second-look operation. Children younger than 1 year tend to have an excellent prognosis; in older children, poorer prognosis is directly proportional to age.

Esophageal Masses

Esophagus-related posterior mediastinal lesions include neoplasm, esophageal cysts,⁴⁵ diverticula, hiatal hernias, megaesophagus, and esophageal varices.⁴⁶ Esophageal disease rarely is seen on chest radiographs. Plain chest radiography usually is normal in patients with esophageal carcinoma though subtle abnormalities sometimes are present, including a retrocardiac mass, abnormal azygos-esophageal recess interface, widened mediastinum, widened retrotracheal stripe, and esophageal air-fluid level. Often these abnormalities are recognized in retrospect once the pathology has been identified by other modalities. Hiatal hernia, seen often in the adult population, is the most common esophageal pathologic process detected on the chest radiograph, although it is only pathologic when accompanied by symptoms such as severe gastroesophageal reflux. As with other posterior mediastinal pathology, CT is reliable in establishing tumor size and assessing invasion of the mediastinum and tracheobronchial tree as well as spread of esophageal carcinoma to the liver, adrenals, and upper abdominal lymph nodes.

Endoscopic ultrasonography (EUS) has become the most accurate imaging modality for locoregional staging in cancer of the esophagus. Fine-needle aspiration capabilities have added an entirely new level of accuracy in regional lymph node staging, with reported accuracy in

the 90% range.⁴⁷ Transesophageal echocardiography (TEE) may be an adjunct in assessing a mediastinal mass, although it should be used in conjunction with CT or MRI for more thorough evaluation. TEE nicely demonstrates impingement of the left atrium or ventricle, which is a common occurrence with posterior masses. Echocardiographers need to be aware of a type of posterior mediastinal encroachment that is common with gastric or esophageal disease, specifically the two-dimensional echo features that may simulate a left atrial mass.⁴⁸

A barium swallow definitively identifies a hiatal hernia, usually a sliding type, that occurs in as many as 15% of symptomatic patients.⁴⁹ An air fluid level seen in a retrocardiac location on a plain chest radiograph often is enough evidence to diagnose a hiatal hernia. This is discussed in detail in the following chapters. The barium swallow also remains the most useful study to clarify the nature of a retrocardiac mass, such as a pseudotumoral venous collateral.⁵⁰ A complete discussion of esophageal cancer can be found in [Chapters 37 to 39](#).

Cysts of the Posterior Mediastinum

Mediastinal cysts form a group of uncommon benign lesions of congenital origin. Cystic lesions of the posterior mediastinum are relatively rare and include bronchogenic, hydatid,⁵¹ enteric, intramural esophageal, and neuroenteric cysts. Thoracic CT is the most effective method for the diagnosis of posterior mediastinal cysts ([Fig. 43-8](#)).⁵²

The significant controversy regarding these cysts is whether to manage them with observation or surgical resection. They are benign lesions in which operation can be performed with a low morbidity and mortality, enabling the surgeon to rule out malignant transformation and to offer a definitive cure.⁵² Reports of uneventful operative courses without recurrence for mediastinal cysts are readily available.^{53,54} Alternatively, many of these cysts may be “treated” by observation only with serial chest radiographs or CT scans.

Bronchogenic Cysts

Mediastinal cysts constitute 20% of all mediastinal masses, and bronchogenic cysts represent 60% of all mediastinal cysts.^{10,55-57} These cysts are part of the spectrum of bronchopulmonary foregut abnormalities that include extralobar and intralobar sequestration and congenital cystic adenomatoid malformations of the lung.

Cystic lesions can be located in the lung parenchyma or mediastinum. On histologic examination, bronchogenic cysts demonstrate a lining composed of ciliated columnar epithelium. The cyst wall may be composed of cartilage, mucus glands, and smooth muscle. They rarely communicate with the tracheobronchial tree.

Symptoms are present in the occasional patient, usually from compression of adjacent structures or recurrent infection. Paraesophageal bronchogenic cysts often are noted incidentally in the posterior mediastinum during routine chest radiography. If the diagnosis of a bronchogenic cyst is made preoperatively and patients are asymptomatic, observation is an appropriate course. If there is

FIGURE 43-8 ■ **A**, Chest film of a pericardial cyst in the right pericardiophrenic angle. **B**, CT image shows the characteristic nearer attenuation of the mass and the typical anatomic location.

any question of malignant transformation based on radiographic appearance, positive results of cytology, or evidence of enlargement or recurrence, the lesion should be resected. The presence of symptoms—especially pain, cough, or hemoptysis—suggests the advisability of resection. Barium swallow study may identify the source of dysphagia due to external compression. The presence of an air–fluid level may indicate communication with the bronchopulmonary tree (rare) and the likelihood of recurrent infection and indicates that resection is in order. Once a bronchogenic cyst has become infected, the infection is difficult to eradicate, and the lesion should be resected.⁵⁸

Symptoms tend to develop with time, and resection at an asymptomatic stage may be best in healthy subjects. A VATS approach provides an ideal method for resection of these benign lesions. Depending on location, specifically if they are in the superior mediastinum, many of these may be resected through the mediastinoscope.⁵⁹ Martinod and coworkers⁵⁶ reported their 3- to 7-year experience with thoracoscopic resection in 10 patients with posterior mediastinal bronchogenic cysts. The average cyst size was 4.9 cm, and the largest diameter was 10 cm. There were no operative deaths and no postoperative complications. Long-term follow-up (range, 4.5 to 7.5 years) showed no late complications and no recurrence.

Gastroenteric Cysts

Gastroenteric or esophageal duplication cysts are peri-esophageal lesions that form from the posterior division of the primitive foregut. They can cause a middle or posterior mediastinal mass, particularly seen in the younger patient. They occur within or adjacent to the wall of the esophagus and rarely communicate with the upper gastrointestinal tract.

On histologic examination, duplication cysts are lined by nonkeratinizing squamous, ciliated columnar, gastric, or small intestinal epithelium. In distinguishing

a bronchogenic cyst from esophageal cysts, the lining epithelium is not helpful, but the presence of two muscle layers in esophageal cysts and bronchial glands or bronchial cartilage in bronchogenic cysts enables categorization in the majority of cases.⁵⁴

Patients can have a variety of symptoms, but these lesions usually are asymptomatic. Respiratory compromise with cough, dyspnea, recurrent pulmonary infections, and chest pain are uncommon. If gastric mucosa is present, perforation into the esophagus can cause hematemesis, or erosion into the adjacent lung parenchyma can develop into an abscess. These complications are exceedingly rare with these lesions.

Diagnosis is facilitated by the use of esophageal ultrasonography, chest CT, or contrast studies of the upper gastrointestinal tract.⁴⁵ Technetium-99m scanning can be used to look for ectopic gastric mucosa. Resection is the therapy of choice, whether by thoracoscopic or open technique. Many of these lesions are amenable to a minimally invasive thoracoscopic approach that still allows complete resection. Posterolateral thoracotomy is the procedure of choice when greater exposure is required. The question always arises as to whether it is necessary to resect these benign lesions. Certainly, resection is indicated if the lesion is producing compressive symptoms or is infected; it is the asymptomatic lesion discovered incidentally that poses the question of whether resection is indicated. It is often unclear whether the lesion is truly cystic because the cyst contents become so inspissated as to appear solid. When the cystic nature of the lesion is unclear, a case can be made for resection, especially through a minimally invasive approach. Observation may be the best approach for asymptomatic lesions that are clearly cystic.

Neuroenteric Cysts

Neuroenteric cysts make up 5% to 10% of foregut lesions. They occur in infants younger than 1 year and

are uncommon in adults.⁵³ They have a connection to the meninges, usually by a stalk, and are associated with congenital defects of the thoracic spine. Neuroenteric cysts possess endodermal and ectodermal or neurogenic elements. They develop because of failure of separation of the notochord from the primitive gut. A CT scan showing a cystic mediastinal lesion associated with a vertebral abnormality such as congenital scoliosis, hemivertebrae, or spina bifida should prompt consideration of a diagnosis of neuroenteric cyst.

Other Masses of the Posterior Mediastinum

Primary or metastatic tumors of the thoracic spine may also appear as a posterior mediastinal paravertebral mass. Lymphomas, particularly Hodgkin disease, can involve the posterior parietal group of lymph nodes and produce a fusiform paravertebral soft tissue mass. Infections such as tuberculosis can result in a paravertebral mass, as can a post-traumatic hematoma. A descending thoracic aortic aneurysm is an important lesion that can masquerade as a mediastinal neoplasm.

Extramedullary hematopoiesis, a compensatory response to insufficient bone marrow blood cell production, is a rare cause of a paravertebral mass.⁶⁰ The preferred sites of extramedullary hematopoietic involvement are the spleen, liver, and lymph nodes. However, in hereditary spherocytosis, for example, the posterior paravertebral mediastinum is also commonly involved. Extramedullary hematopoietic tumors can occur without severe chronic hemolytic anemia. Therefore, this lesion must be considered in the differential diagnosis of a posterior mediastinal mass in patients even without clinical evidence of anemia.⁶¹ Earlier reports demonstrated the utility of a conventional chest radiograph and CT scan of the thorax for diagnosis without biopsy or thoracotomy.⁶² Later reports clarify the superiority of MRI in identifying intrathoracic extramedullary hematopoiesis, although it usually is used in conjunction with CT because of specific limitations.^{60,63}

Castleman disease (giant lymph node hyperplasia) is characterized by mass lesions that are vascular tumors often surrounded by lymphadenopathy (Fig. 43-9).^{64,65} This arrangement makes lymph CT useful diagnostically because CT can reveal lymphadenopathy surrounding an encapsulated mass that enhances brightly and is distinct from the aorta. The term is applied to three lesions that are histologically distinct: hyaline vascular, plasma cell, and generalized. The first two represent localized disease, whereas the third refers to multicentric (generalized) disease.

Hyaline vascular Castleman disease accounts for 90% of cases; it is a localized lesion usually found incidentally in asymptomatic patients. Castleman disease manifesting as a spinal epidural mass lesion with cord compression has been reported.⁶⁶ Surgical excision is the treatment of choice; radiotherapy has not been effective. The plasma cell variant, also localized, is much less common. Patients are much more likely to have symptoms and to exhibit fever, fatigue, weight loss, and hemolytic anemia. The sedimentation rate is often high and is associated with

hypergammaglobulinemia, which results from the production of interleukin-6 by the hyperplastic lymph nodes. Resection is the treatment of choice.

Generalized or multicentric Castleman disease has the histologic features of both localized forms. The disease occurs in older patients, who typically present with severe systemic symptoms, generalized lymphadenopathy, and hepatosplenomegaly. The mortality from this disease is 50%, and the median survival is 27 months. Progression to lymphoma is common (see Fig. 43-8). The diagnosis of lymphoma is made from a sample of the lesion and treatment is directed at management of the lymphoma.

Other rare causes of a primary posterior mediastinal mass most commonly occurring in the paravertebral sulcus include angiomyolipoma,^{67,68} extralobar pulmonary sequestration,⁶⁹ neuroendocrine carcinoma,⁷⁰ mediastinal ependymomas,⁷¹ cellular hemangiomas,⁷² melanotic paraganglioma,⁷³ and mediastinal extension of a pancreatic pseudocyst.

INFECTIONS OF THE MEDIASTINUM

Descending necrotizing mediastinitis is a potentially fatal condition in its acute or chronic form that can involve the posterior mediastinum.⁷⁴ Acute mediastinitis most commonly occurs after postoperative infection or esophageal perforation. The organism most commonly isolated is *Staphylococcus* spp. In acute mediastinitis, the patient presents with the typical signs of infection, including fever, tachycardia, and leukocytosis. Subcutaneous emphysema resulting from esophageal perforation may be another clue to an infectious source.^{74,75} In chronic mediastinitis, the etiology is a granulomatous infection. When the granulomas rupture, the contents lead to a fibrotic reaction.

The posterior mediastinum is more susceptible to infection than the other compartments of the thorax. Anatomically, this is explained by the relative accessibility and communication of the posterior mediastinum to the neck and abdomen. Inferiorly, the hiatus for the inferior vena cava and the hiatus for the aorta traversing the diaphragm are well sealed; however, the esophageal hiatus, which is the furthest posterior, is not closed as well, and it provides a track between the posterior mediastinum and the abdominal cavity. Similarly, infections from the head and neck have easy access to the posterior mediastinum. The more anterior fascial planes that arise from the neck terminate before reaching the mediastinal compartments. Two posterior spaces communicate directly with the pharynx, neck, and mediastinum. The first space is located between the visceral fascia and the alar fascia and is termed the *danger space* because of its direct communication with the posterior mediastinum. The second space is located between the prevertebral fascia and the vertebral bodies, allowing communication of vertebral infections.⁷⁴

Not surprisingly, abscesses are more frequent in the posterior mediastinum than in the anterior compartment (Fig. 43-10). Although primary infection is possible, most infections are secondary and the source usually is readily apparent. Most common signs of posterior mediastinal

FIGURE 43-9 ■ **A** and **B**, Chest films of a giant lymph node hyperplasia (Castleman's disease) that occurs in the posterior mediastinum. **C**, CT image of the tumor is similar to a neurogenic tumor. **D**, Photomicrograph of the tumor shows the small hyaline follicles and interfollicular capillary proliferation that are characteristic of the hyaline vascular form. **E**, Photograph of a gross specimen.

abscess are pain, dysphagia, cough, and dyspnea. The pain occurs most often on swallowing and coughing, and it is felt posteriorly in the interscapular region or may radiate anteriorly. The symptoms are due to encroachment on the esophagus and trachea in the upper part of the chest. Esophageal perforation is the most common cause of a posterior mediastinal abscess, and it is often fatal if not recognized and treated expeditiously. Another cause of posterior mediastinal abscess is extension of infection from the oropharynx, spine, lung pleura, or abdominal cavity.

CT scan may demonstrate an air–fluid level or mediastinal air as part of an otherwise solid-appearing mass (Fig. 43-11). Nonsurgical management, which occasionally may be appropriate if there is no ongoing leak, includes intravenous antibiotics, but surgical drainage and débridement usually is required on an urgent basis. Surgical intervention includes widely opening the mediastinal compartment by incision of the pleura followed by débridement, irrigation, drainage, and closure of the esophageal perforation with or without a muscle flap. In diffuse mediastinitis involving the posterior

mediastinum, pericarditis or bilateral exudative pleuritis may be present.

SUMMARY

Lesions of the posterior mediastinum most commonly are neurogenic in origin and usually are benign in adults. Despite this recognition, surgical intervention commonly is required. Minimally invasive surgical approaches can provide additional justification for removal of these lesions before they become symptomatic.

OTHER SURGICAL TREATMENTS FOR HYPERHIDROSIS

CONCLUSION

Hyperhidrosis is a pathologic condition characterized by excessive sweating beyond what is required for normal physiologic thermoregulation. This overproduction causes a significant psychosocial affliction that can negatively affect an individual's quality of life. The incidence of hyperhidrosis depends on the culture, on the climate, and on subjective definitions. Hyperhidrosis affects 1% to 3% of the U.S. population, but this percentage is likely underestimated because of infrequent reporting by patients and incorrect diagnosis by physicians.¹ Hyperhidrosis affects both sexes equally, affects predominantly adolescents or young adults, and can affect multiple body sites. Characteristically, the palmar symptoms start in early childhood, axillary symptoms in adolescence, and craniofacial symptoms in adulthood; puberty usually worsens the symptoms.

Hyperhidrosis is a primary (idiopathic) or secondary disorder with localized or generalized sweating. Focal or primary hyperhidrosis is excessive sweating not associated with a systemic process and usually affects the palms, axillae, or feet. Additionally, some patients may have craniofacial hyperhidrosis, or excessive blushing that is associated with severe emotional, occupational, and social distress. Hyperhidrosis can develop secondary to various medical disorders, such as hyperthyroidism, hypertension, diabetes mellitus, systemic infections, brain lesions, and certain medication use. Systemic medical conditions need to be diagnosed correctly and treated medically and should not be treated with surgery. Also, patients who are overweight (a body mass index > 28) may have full-body or secondary hyperhidrosis.²

Eccrine sweat glands are responsible for hyperhidrosis.³ Eccrine glands are innervated by the sympathetic

nervous system but use acetylcholine as the primary neurotransmitter. Thermal sweating is controlled by the hypothalamus, whereas emotional sweating is regulated by the cerebral cortex. A sympathetic signal is carried to sweat glands by cholinergic autonomic neurons. In patients with primary hyperhidrosis, the sweat glands are usually histologically and functionally normal. Although the pathophysiology remains unknown, the cause of hyperhidrosis appears to be an abnormal central response to emotional stress, but it can also occur spontaneously and intermittently. Additionally, there is evidence for a genetic component to hyperhidrosis, and it can be seen in family members.⁴ A genetic analysis suggests that an allele for hyperhidrosis may be present in 5% of the population.

There remains significant controversy concerning the optimal surgical therapy for primary hyperhidrosis. That is partially because of the poor definitions of the terms used for both the diagnosis of the problem and the surgical therapy. For example, video-assisted thoracic surgery (VATS) sympathectomy goes by other names, such as endoscopic thoracic sympathectomy (ETS) or sympathotomy. These terms are not synonymous. Sympathectomy and ganglionectomy refer to total ablation or removal of a segment of the sympathetic chain and ganglia, or both. Sympathicotomy and sympathotomy refer to interruption or simple transection of the sympathetic chain. Sympathetic block refers to a potentially reversible procedure, such as clipping of the sympathetic chain or local anesthetic injections of the nerve. Selective sympathectomy refers to preservation of the sympathetic chain with ramicotomy (division of the rami communicantes). To help clarify these controversies, the Society

of Thoracic Surgeons (STS) Task Force on Hyperhidrosis published an expert's consensus paper for the surgical treatment of hyperhidrosis that suggested the adoption of a standard international nomenclature that refers to the rib level (R) instead of the vertebral level at which the nerve is interrupted, how the chain is interrupted, along with systematic pre- and postoperative assessments of sweating pattern, intensity, and quality of life.⁵ This report also established specific treatment strategies regarding sympathectomy for distinct patterns of hyperhidrosis.

NOMENCLATURE FOR SYMPATHETIC SURGERY

The International Society on Sympathetic Surgery (ISSS) and the STS Task Force on Hyperhidrosis decided that an internationally agreed upon nomenclature was needed. It has often been unclear exactly where and how a surgeon interrupted the chain, which has made it almost impossible to compare techniques and results. The nomenclature needs to include the location where the sympathetic chain is interrupted and the method of how it is interrupted. Various anatomic landmarks exist to guide the surgeon in determining the exact level where to divide or clip the chain or ganglia for a sympathectomy. The ISSS and STS committees' consensus used a rib-oriented nomenclature. This decision was based on too many patients having mediastinal fat that can obscure clear identification of the specific ganglia and on the multitude of anatomic variations in the ganglion anatomy. The surgeon may add the ganglia that are interrupted to the operative note as well. In addition, the committees agreed that a description of the type of interruption is required denoting whether the chain was clipped, cut, or cauterized or whether a segment was removed.

At operation, therefore, the level is abbreviated as an R3 or an R4 (R referring to rib, and the number referring to which rib). If the chain is clipped on top of the second rib, the abbreviation for the operative note would be "clipped R2, top." If the chain is cauterized on the top and bottom of the fourth rib, the operative note would be "cauterized, top R4, bottom R4." Using this standardized nomenclature would allow surgeons worldwide to better communicate with one another.⁵

The literature on sympathectomy for hyperhidrosis must be interpreted cautiously because the definitions can differ from paper to paper. Some studies use objective data such as hand temperature postoperatively to determine success, whereas others simply rely on subjective reporting by the patient. Not all studies assess compensatory hyperhidrosis (CH) similarly, or at the same point postoperatively, or quantify the degree of CH. Standardized preoperative and postoperative questionnaires are needed to objectify the improvement of these patients. One of the best data collection sheets was developed and used by De Campos and associates⁶ in an effort to standardize results. Follow-up is a critical part of hyperhidrosis treatment. It is recommended that patients have follow-up appointments or surveys at 1 month, 6 months, 1 year, and annually for at least 5 years if possible.

PATIENT SELECTION FOR VATS SYMPATHECTOMY

The ideal candidates for VATS sympathectomy are those who have onset of hyperhidrosis at an early age (usually before 16 years of age), are young at the time of surgery (usually younger than 25 years old), have an appropriate body mass index (<28), report no sweating during sleep, are relatively healthy (no other significant comorbidities), do not have bradycardia (resting heart rate < 55 beats/min), and have no associated body sweating.

Only a small percentage of patients should be considered for surgical treatment. Surgical consultation should include the correct diagnosis of primary hyperhidrosis, the anatomic locations involved, the amount of hyperhidrosis, and full discussion of the surgical options and potential complications. The patients should be made aware that the most satisfied patients are those with palmar or palmar-axillary hyperhidrosis, or both. Finally, patients should also be told of the success and failure rates and long-term results. Physicians can offer the patient the option to discuss the procedure and its side effects with a patient who has already undergone the surgery. This can be done by a conference call under the Health Insurance Portability and Accountability Act (HIPAA) guidelines or face to face at the patient's request.

Prior to any surgical procedure, patients must fail conservative medical therapy. Most insurance companies require a patient to fail at least three nonsurgical treatments. First-line treatment is usually prescription-strength antiperspirants, which work by mechanical obstruction of the eccrine sweat gland ducts or by causing atrophy of the secretory cells. These include antiperspirants with 20% aluminum chloride in ethanol (Drysol) or 6.25% aluminum tetrachloride (Xerac). Drawbacks to using these agents include dyspigmentation of skin, contact dermatitis, and necessity for continuous use. Systematic medication may also be used in the treatment of hyperhidrosis. Anticholinergic agents (glycopyrrolate, propantheline, oxybutynin) are the most commonly used, but the dosage required to reduce sweating causes significant side effects such as dry mouth, blurred vision, and urinary retention. In patients with hyperhidrosis triggered by specific emotional events, beta blockers or benzodiazepines may be useful for reducing the emotional stimulus that leads to excessive sweating. Long-term use of these oral agents is not advisable, and rebound sweating may be more severe with withdrawal of the medication than it is with the baseline hyperhidrosis.

Iontophoresis may be used. It is the introduction of ionized substances through the intact skin by the application of a direct electrical current. Iontophoresis is most often used for palmar or plantar hyperhidrosis; a special axillary electrode can also be used but is less effective. There are limited data from randomized trials, but iontophoresis appears to alleviate symptoms in approximately 85% of patients with palmar or plantar hyperhidrosis.⁷ The drawbacks are the upfront machine cost, the labor intensiveness of the treatment, irritation of the skin with scaling and fissuring, and, primarily, the pain associated with the daily treatment sessions.

Botulinum toxin type A (Botox) and type B (Myobloc) have been shown to be effective for axillary and palmar hyperhidrosis, although Botox has not been approved by the Food and Drug Administration (FDA) for palmar treatment. Botox blocks the release of acetylcholine from the presynaptic junction of the autonomic neurons and temporarily reduces sweat production. The effect usually lasts for 3 to 4 months. Long-term results with repeated injections for more than 2 years is infrequent because of antibodies produced against the toxin.⁸ Drawback includes pain at the injection sites, transient hand weakness, and high treatment cost.

Surgical therapy is extremely effective for medical refractory primary hyperhidrosis and is based on the interruption of transmission of impulses from the sympathetic ganglia to the sweat glands. Currently, a VATS approach is preferred. The literature on sympathectomy for hyperhidrosis must be interpreted cautiously because of non-uniform definitions of sympathetic chain levels treated, of successful treatment, and of the incidence of post-sympathectomy CH.

LOCATION OF INTERRUPTION OF SYMPATHETIC CHAIN

Palmar Hyperhidrosis

Opinions differ on how to treat patients who have only palmar hyperhidrosis. For patients who are willing to accept a higher risk of CH because they want their hands to be completely dry, it is suggested that two interruptions in the sympathetic chain be made, at R3 and R4. However, based on a prospective randomized study in 2009 by Liu and associates⁹ and a study in 2007 by Yang and colleagues,¹⁰ an R4 alone interruption may be acceptable for these patients because it limits the degree of CH; however, it may lead to moister hands. The patients should be counseled about these differences and should participate in the decision-making process. For these reasons, the top of R3 sympathectomy alone for patients with isolated palmar hyperhidrosis is recommended.

Patients with palmar and plantar hyperhidrosis represent a different challenge. Again, two operations can be performed. An R4 interruption alone may reduce the incidence of CH. Alternatively, an R4 and R5 intervention is a reasonable option; because this intervention results in drier feet, it is the preferred treatment.

Axillary Hyperhidrosis

VATS sympathectomy for axillary hyperhidrosis is often less successful and has higher “regret rates” than sympathectomy for palmar hyperhidrosis. A qualitative review showed a trend of lower incidence of CH with fewer interruptions, even when the interruptions are fairly low on the chain.^{11,12} In a randomized, prospective study of patients with axillary hyperhidrosis, Munia and colleagues¹³ in 2008 showed that all (100%) patients who underwent R3/R4 ETS experienced greater incidence and severity of CH, 1 year after surgery, compared with patients who underwent R4 ETS alone (42%). Chou and

associates¹⁴ found that patients with axillary hyperhidrosis who underwent R5 clipping alone experienced no CH, and none regretted having the surgery. Therefore, for patients who have palmar-axillary, palmar-axillary-plantar, or pure axillary hyperhidrosis, an R4 and R5 transection is recommended.

Craniofacial Hyperhidrosis

Patients with cranial and facial sweating present a more complicated problem compared with patients who have hyperhidrosis that affects the lower part of their body. Chou and colleagues¹⁴ in 2006 reported an experience with R3 interruption of the chain in 33 patients with craniofacial sweating. They found that only 3 patients (9%) regretted the procedure and 9 (27%) reported CH. In that same series, Chou and colleagues also performed R2 interruption in 54 patients with facial blushing. More than 40% of these patients experienced CH, and 16.7% of patients regretted having the operation. Licht and coworkers¹⁵ in 2006 compared R2 interruption with R2 and R3 interruption in 173 patients with facial blushing. They found a significantly higher CH rate in the group that underwent the R2 and R3 transection (95%) compared with the R2 group (83%). Craniofacial sweating must be distinguished from blushing. Based on the findings of these and other series, an R3 alone interruption is suggested for craniofacial sweating, because it reduces the risk of CH and the risk of Horner syndrome when compared with R2 or an R2 and R3 transection.

TYPE OF INTERRUPTION

Should the sympathetic chain be resected, transected, ablated with cautery, or divided with a harmonic scalpel, or should clips be used? No clear differences have been demonstrated among the different techniques; when the correct level of division is achieved, the results are excellent and reproducible. The most important concept about nerve disruption is that there is enough separation (>1.0 to 1.5 cm) between the ends of the chain so that regrowth is impossible. By just ablating the nerve, it is more than likely to regrow, and symptoms could reoccur. Also, accessory nerves (Kuntz) must also be interrupted to prevent persistent excessive sweating or recurrence. Despite initial enthusiasm, the presumption that the patient can return for “surgical reversal” by removing the clip appears questionable. Clip removal for reversible of postprocedure CH has shown disappointing results at long-term follow-up, which is more than likely because of permanent perineural damage to the sympathetic chain secondary to multiple clips, which is usually irreversible.¹⁶

SURGICAL TECHNIQUE (see Video 44-1)

VATS Sympathetic Block

A temporary VATS sympathetic block is performed as an outpatient procedure within our hospital's main

operating room or in our ambulatory surgical center. The patients are placed in a supine position. General anesthesia is initiated with a single-lumen endotracheal tube, usually 7.0 or 7.5 Fr. After the patient is asleep, the arms are extended laterally to 90 degrees. Excessive abduction of the upper extremities is avoided to prevent injury to the brachial plexus. Temperature probes are placed on each index finger. Each axilla is prepped in standard fashion. Attention is first directed to the right side. A single 4-mm incision is made vertically over the fourth rib along the midaxillary line. Using a mosquito clamp, the chest cavity is entered over the fourth rib during suspension of ventilation. During continued ventilation suspension, a 3-mm 30-degree rigid thoracoscope (Karl Storz, Munich, Germany) is placed. Alongside the thoracoscope, a standard laparoscopic Veress needle (Ethicon, Inc., Cincinnati, OH) is also placed. After the two instruments are placed without difficulty, ventilation is resumed with a decreased tidal volume of 250 mL for women and 300 mL for men. Temporary CO₂ insufflation is carried out to 10 mm Hg for approximately 30 to 90 seconds to allow partial collapse of the lung. The apical and posterior chest is examined in detail to allow accurate identification of the anatomy of the sympathetic chain and its accessory nerves.

Prior to performing the block, a finger temperature is recorded as a baseline measurement. The block is performed by placing a 2-mm hollow semi-rigid catheter alongside the thoracoscope to the apex of the chest under direct visualization. A 22-gauge laparoscopic needle is then placed through the catheter. The sympathetic chain is injected with 2.5 mL of 0.25% Marcaine with epinephrine at each planned sympathectomy site and 1.0 mL at each accessory nerve. After completion of the block of the primary nerve and its accessories, a postblock temperature is taken at 5 minutes. The needle is removed, and the external end of the catheter is placed in a basin of sterile water to create a water seal. The pneumothorax is evacuated by immersing the catheter in sterile water, adjusting positive pressure ventilation to 40 mm Hg, and suctioning. After the pneumothorax is evacuated, the catheter is removed. The skin is reapproximated with a Dermabond adhesive. The left side is completed in a similar fashion. A dose of 15 mL 0.25% Marcaine is injected into each incision prior to making the incision and at the time of closure. Also, 30 mg of ketorolac is given intravenously prior to making the incision. The patient is taken to the recovery room for an upright chest radiograph and subsequent planned dismissal.

VATS Sympathicotomy

The subsequent sympathectomy is usually performed within 4 weeks of the VATS block procedure. Again, the procedure is performed as an outpatient surgery within our hospital's main operating room or in our ambulatory surgical center. Redo single 4-mm bilateral incisions are made, incorporating the previous incisions. Again using a mosquito clamp, the chest cavity is entered over the fourth rib during suspension of ventilation. During continued ventilation suspension, the thoracoscope and Veress needle are placed. After the two instruments are

FIGURE 44-1 ■ Video-assisted thoracic surgery (VATS) scar 4 weeks after surgery.

placed without difficulty, ventilation is resumed. Temporary carbon dioxide insufflation is carried out. The Veress needle is removed, and through the same incision alongside the thoracoscope, a 2-mm-long electrocautery device is placed. Again, a detailed examination is carried out of the apical and posterior chest to accurately identify the anatomy of the sympathetic chain and its accessory nerves. Prior to the sympathectomy, a finger temperature is taken for a baseline measurement. The sympathetic chain is then divided over the second, third, or fourth rib to complete the planned sympathectomy (depending on preoperative indication, T2 only, T3 only, or T3/T4) with a 2-mm-long electrocautery device. All accessory nerves are also divided with electrocautery. The cauterized ends of the nerves are separated from each other to allow at least a 1.0- to 1.5-cm gap to diminish the chance of regrowth and possible recurrence of hyperhidrosis. The external end of the catheter is placed in a basin of sterile water to create a water seal, and the pneumothorax is evacuated as described earlier. After the pneumothorax is evacuated, the catheter is removed. The skin is reapproximated with a Dermabond adhesive. The left side is completed in similar fashion. A dose of 15 mL 0.25% Marcaine is injected into each incision prior to making the incision and at the time of closure. In addition, 1000 mg of acetaminophen and 30 mg of ketorolac are given intravenously prior to making the incision.

In the recovery room, an upright chest radiograph is obtained approximately 30 minutes after completion of the procedure. If the chest radiograph is satisfactory and the patient has minimal discomfort, the patient can be discharged. The patient is asked to return to the clinic within 3 to 4 weeks after the procedure for follow-up. Postoperative scarring is minimal (Fig. 44-1).

COMPLICATIONS AND TREATMENT

Because the goal of the surgery is to improve the patient's quality of life, complications should be minimal and essentially eliminated. The primary side effects of hyperhidrosis surgery include CH, bradycardia, and Horner syndrome. It is important for patients to be aware, however, of all possible complications that can occur.

The most common side effect is CH, which, according to the literature, occurs in 3% to 98% of cases.^{17,18} This wide variability in the incidence of CH may be attributable to heterogeneous patient populations, different surgical procedures, or, more importantly, a variety of definitions of CH. The clinical presentation of CH can be classified as mild, moderate, or severe.⁹ Mild CH is sweating that occurs in small amounts and is triggered by ambient heat, psychological stress, or physical exercise. The sweat that forms does not flow, is tolerable, and does not cause embarrassment or the need to change clothes. Moderate CH is when sweating occurs in moderate amounts and is triggered by ambient heat, psychological stress, or physical exercise. The sweat coalesces into droplets that flow, although not necessitating a change of clothes. Therefore, the sweating, although uncomfortable, does not embarrass the patient. Severe or intense CH is when sweating occurs in large amounts and is triggered by low or no ambient heat, psychological stress, or physical exercise. With severe CH, the sweat droplets form profusely, requiring a change of clothes one or more times a day. If the patient is already experiencing increased sweating in the trunk, groin region, or upper thighs, then the patient should be warned that he or she is at increased risk of developing CH, and the patient should think twice about proceeding with the procedure.

The most common risk factor cited in the literature for moderate to severe CH is interruption of T2 ganglion (R2, R3).^{10,19} The number of levels interrupted has been inconclusive as a risk factor.^{20,21} Some techniques have been described to help predict or minimize the degree of CH. A reversal sympathetic block technique with bupivacaine hydrochloride was developed by Miller and associates in 2007 for patients who are at an increased risk for CH.²² This technique has been useful for predicting which patients may develop severe debilitating CH. If the patient does not have bothersome CH and has cessation of the hyperhidrosis, then nerve transection is performed at a later date. Other options to help treat patients with CH include use of medication (Ditropan or other anticholinergic medications) in escalating doses and liposuction of the axillary sweat glands. Gustatory sweating may also occur, but rarely, in less than 0.1% of patients.

Horner syndrome is another side effect that has been reported to occur at a rate between 0.7% and 3% after VATS sympathectomy. The possibility of Horner syndrome should be addressed in patients with craniofacial hyperhidrosis, as direct injury by cautery, traction, or surrounding inflammation can occur as a result of improper localization of the second rib. In all series, inadequate localization decreases with surgical experience. The risk of this complication may be minimized with procedures performed below the second rib (R2), although indirect injury may still result. Misidentification of the operative level can occur; some recommend that an intraoperative radiograph be performed if the anatomy is uncertain. Anatomically, the stellate ganglion can be lower on the left side down to R3.

Permanent bradycardia has been reported after surgery for hyperhidrosis as well.²³ This issue needs to be fully discussed with patients who come in with a resting heart rate less than 55 or 50 beats/min because there have been

reports of patients who may require a pacemaker. Patients who are highly competitive athletes who may require compensatory increase in heart rate or vascular tone with exercise should be told that their exercise capacity could theoretically be reduced and should be encouraged to drink large quantities of electrolyte-containing fluids while participating in sports.

Other less common complications (1%) include pneumothorax requiring chest tube drainage, pleural effusion, acute bleeding or delayed hemothorax, chylothorax, and persistent intercostal neuralgia. Bleeding and pain complications can be reduced by careful port placement²⁴ or no port placement at all as described by Miller and Force.²⁵ Pneumothorax can also be minimized with careful attention to avoiding parenchymal injury during initial port placement as well as to the technique of reinflation.

Recurrent hyperhidrosis is another potential side effect from hyperhidrosis surgery. Incidence rates vary considerably and have been described as 0% to 65%.²⁶ This wide variability may be a result of the differences in the techniques used, the levels of the sympathetic chain interrupted, the definitions used, and the length of follow-up. The primary reason for failure is inadequate surgery. That can be attributed to an anatomic variation in the sympathetic chain, surgical technique, intense pleural adhesion, presence of vessels overlying the sympathetic chain or aberrant venous arch drainage, abundant adipose tissue, and possible reinnervation, especially in children who grow after the procedure. Resympathectomy has been advocated and successfully performed, mainly for immediate failures. Adhesions from the first operation have been the most frequently reported reason for avoiding resympathectomy.²⁷ Analyzing the previous medical records and operative notes is essential before performing the second operation.

OTHER SURGICAL TREATMENTS FOR HYPERHIDROSIS

Other surgical therapies for axillary hyperhidrosis are the removal of the axillary sweat glands by means of curettage²⁸ or liposuction.²⁹ Complications include wound infection, scar formation, skin necrosis, and skin discolorations. The VASER (Sound Surgical Technologies, Louisville, CO) is a third-generation FDA-approved ultrasound device that allows emulsification of axillary tissue and glands. Primary side effects include transient dysesthesia, indurations, seroma, and ecchymosis.³⁰ All of these procedures take approximately an hour to perform and can be performed in the office.

CONCLUSION

VATS sympathectomy for medical refractory primary hyperhidrosis is extremely successful. Interruption of the chain can be achieved by cauterizing, cutting, or clipping the sympathetic chain. Although the level of interruption, based on the patient's distribution of the hyperhidrosis, remains controversial, standardized

anatomic classifications and careful literature review provide the best framework for treatment strategies. A thorough preoperative workup, attention to detail at the time of the nerve interruption, an understanding of the levels that should be interrupted, and comprehensive education of the patient about treatment options, success rates, and complications will lead to a satisfied patient with a significant improvement in quality of life. These results are also dependent on the weather, the climate, physical and work activities, psychological aspects, and other specific conditions of the patient.

SUMMARY

As Dr. Blake Cady eloquently stated, tumor biology is the principle determinant of outcome in surgical oncology.

“Biology is King, Selection is Queen, and the technical details of surgical procedures are the Princes and Princesses of the realm who frequently try to overthrow the powerful forces of the King and Queen, usually to no long-term avail, although with some temporary apparent victories.”¹

Reflections such as this and our clinical experience highlight that our ability to make a significant, lasting impact on the outcomes of most cancer patients rests in our capacity to understand and influence tumor biology.

A revolution in the care of patients with thoracic malignancies is upon us. The clinical application of molecular diagnostic and analytic technologies is growing rapidly, and recent studies have begun to unfold their true potential for thoracic oncology patients. In particular, genetic science has a possible role in guiding therapy (based on both an individual's risk of recurrence and death and a tumor's genetic features) and counseling

patients (with regards to risk of recurrence and prognosis). Indeed, as our understanding of tumor biology continues to evolve, effective personalized oncology is becoming a reality. In this chapter, we provide a brief review of our current understanding of the molecular mechanisms underlying oncogenesis and metastases of thoracic malignancies. We also highlight the current role of epigenetics, proteomics, biomarkers, and personalized oncology in the care of patients with thoracic malignancies.

MECHANISMS OF ONCOGENESIS AND METASTASIS

The progression of a cell from normal to overt malignancy is the end result of a complex sequence of genetic events influenced by a number of environmental and biological factors. The precise mechanism of oncogenesis of thoracic malignancies is complex and incompletely understood (Fig. 45-1). However, a few salient points have emerged from the literature.

FIGURE 45-1 ■ Overview of the pathways involved in oncogenesis.

Environmental Exposure

First, most thoracic malignancies are the end result of the effect of an environmental exposure (e.g., tobacco smoke, alcohol use, chronic gastroesophageal reflux, asbestos) on a cell's genome. Such exposures can cause alterations in DNA structure (e.g., pyrimidine dimers and double-strand breaks), which can alter DNA replication and transcription. Environmental exposures can also induce mutations if errors are introduced by DNA repair mechanisms while attempting to correct mistakes in DNA structure. Other carcinogens (e.g., asbestos), however, cause chromosomal loss, gain, and/or rearrangements before causing genetic mutations.^{2,3}

Genetic Mutations

Second, mutated genes contribute to oncogenesis by selectively conferring a growth advantage to cancer cells. Such mutations can be either inherited (*germline*)

mutations or acquired (*somatic*) mutations. *Proto-oncogenes* are dominant genes that encode proteins that are responsible for cell-cycle progression, cell differentiation, or regulation of *apoptosis* (programmed cell death). When proto-oncogenes are mutated (by point mutations, translocations, gene amplifications, gene insertions, or gene deletions), they are called *oncogenes*, which are either constitutively active or abnormally active (under conditions that the normal wild-type gene is not).⁴

Tumor-suppressor genes are the genetic brakes on aberrant cell proliferation by regulating cell division, DNA repair, and apoptosis. In contrast to oncogenes, tumor-suppressor genes are recessive genes—both copies need to be inactivated for their effect to be lost. One allele is typically lost through loss of heterozygosity, and the other is typically lost by a mutation or epigenetic modification (discussed later).⁵ Mutations in tumor-suppressor genes confer a growth advantage by removing a normal checkpoint in cellular proliferation.

Mismatch repair genes are recessive genes involved in repairing mistakes occurring primarily during DNA replication. Because microsatellites (tandem repeats in DNA sequences) are especially vulnerable to DNA replication mistakes, *microsatellite instability* is a hallmark of defective DNA repair.^{5,6} To appreciate the interaction among proto-oncogenes, tumor suppressor genes, and mismatch repair genes, these genes have also been subclassified as gatekeepers, caretakers, and landscapers.

Gatekeepers are oncogenes and tumor suppressor genes that control cell growth and differentiation.^{7,8} In contrast, *caretakers* (i.e., tumor suppressor genes and mismatch repair genes) are responsible for maintaining the genomic integrity of the cell. Mutations in caretaker genes promote oncogenesis indirectly by inciting genetic instability, which increases the rate of mutations of other genes (including gatekeepers).^{7,8} If these mutations result in a selective advantage toward cell proliferation (or repression of apoptosis), tumor formation may ensue. Finally, *landscapers* are not directly involved in cellular growth. Rather, they foster a stromal environment conducive to unregulated cell proliferation.^{8,9} Indeed, although normal stroma creates an environment with innate antitumor properties, inherited or acquired mutations in landscaper genes facilitate tumor growth by removing the natural antagonism of the stroma toward oncogenesis (e.g., by altering cell adhesions, cellular signaling, and altered innate immunity) or by altering the microenvironment to a more oncogenic state (e.g., through matrix metalloproteinases and angiogenesis).¹⁰

Heterogeneity of Mutations

Third, not all genetic mutations that accrue during tumorigenesis are equipotent—some mutations involved in cancer progression are more significant than others.¹¹ As oncogenesis progresses, cancer cell proliferation becomes increasingly reliant on these more potent (driver) mutations, a phenomenon known as *oncogene addiction*.^{12,13} Because of a tumor's reliance on the products of these critical oncogenes for growth and survival, this dependence is a point of weakness (an Achilles heel in the seemingly impenetrable armor of unrestrained genetic activity) and, therefore, a potential therapeutic target.^{12,13}

Driver mutations, which comprise a minority of mutations in cancer, are mutations that have been positively selected during oncogenesis by conferring a growth advantage to the cancer cell. They “drive” cancer cell proliferation. In contrast, *passenger mutations*, which comprise the majority of mutations in cancer cells, confer no such advantage. They are simply the expected functional consequence of normal clonal and subclonal expansion.¹⁴ In other words, passenger mutations are simply “along for the ride.” To have a positive therapeutic effect on tumor biology, one must sort through the passenger mutations and devise means to target the driver mutations effectively.

Most genetic mutations found in tumors are clonal (they are present in all cells within the tumor). However, subclonal mutations are an important source of intratumoral, intermetastatic, intrametastatic, and interpatient

tumoral heterogeneity.¹⁵ This source of heterogeneity has significant treatment implications.

Intratumoral heterogeneity refers to heterogeneity of tumor cells within the same tumor.¹⁵⁻¹⁷ Each time a tumor cell divides, the progeny cells acquire new mutations that distinguish them from their common progenitor cells. Therefore, in the process of cell replication down the genetic tree of oncogenesis, cells that are generationally divergent will also be more genetically distinct. From a practical standpoint, this form of heterogeneity is usually not clinically significant in patients with localized disease because the primary tumor is often surgically removed. However, this divergence down the genetic tree of oncogenesis spawns the seeds of intermetastatic heterogeneity.¹⁵

Intermetastatic heterogeneity refers to heterogeneity among spatially distinct metastatic lesions in the same patient.¹⁵ Most patients who die from cancer die from an overwhelming tumor burden in metastatic sites that cannot be removed surgically and that fail systemic chemotherapy or radiation therapy. As such, this form of heterogeneity has significant clinical implications. At one end of the spectrum, if each metastatic site is sufficiently genetically distinct to respond differently to chemotherapeutic agents, then long-term survival is nearly impossible to achieve. Fortunately, most intermetastatic heterogeneity is confined to passenger mutations. The mutations required for metastasis are present in the progenitor cells before the seeds of metastasis are released.¹⁵

Similar to the heterogeneity within the primary tumor that develops during the process of tumor cell propagation (intratumoral heterogeneity), *intrametastatic heterogeneity* is the end result of genetic mutations that occur as a founding cell of a metastatic site divides.¹⁵ Such mutations are the grounds for drug resistance. Metastatic deposits may initially respond to treatment that targets mutations that occurred in progenitor cells before metastases occurred, because many of the cells in a metastatic lesion have the same susceptibility to chemotherapy, evidenced by a decrease in the size (or complete resolution) of the lesion noted on posttreatment medical imaging. However, hundreds or thousands of the cells with acquired drug resistance are likely still present, perhaps below the resolution of medical imaging or clinical examination. Recurrence in such situations is inevitable.

There is also heterogeneity of the same tumor type between different patients (*interpatient heterogeneity*).¹⁵ This form of heterogeneity is responsible for the clinical observation that “no two cancer patients are the same.” As a result, uniformly applying the same systemic treatment to all patients with the same type of tumor does not result in the same response rates for each patient. Even if the end result is the same in two different patients (e.g., a particular driver mutation that leads to lung cancer), the mutations in each patient are likely sufficiently distinct such that they alter the coding sequence of the gene and hence the translated protein product of the gene in unique ways. Even small differences in a protein product can affect the conformation of the protein and hence its susceptibility to treatment. This heterogeneity is likely the result of host factors (e.g., inherited mutations that predispose to developing cancer,

mutations that affect the pharmacokinetics of chemotherapeutic agents, environmental factors within a host that facilitate tumor propagation) and distinct mutations between different tumors that develop during clonal and subclonal expansion.

DNA Aneuploidy

One of the most common observations in solid tumors is *DNA aneuploidy* (abnormal chromosome number and content). Aneuploidy can result from aberrant mitotic divisions, chromosome cohesion defects, improper attachments of chromosomes to microtubules, weakened mitotic checkpoint signaling, or mutated mitotic checkpoint genes.^{18,19} The contribution of aneuploidy to oncogenesis is controversial. Aneuploidy may simply facilitate (rather than directly cause) oncogenesis. For instance, populations of cells that are capable of redistributing chromosomes such that there is an increased probability of loss of heterozygosity (and hence loss of function of tumor-suppressor genes) or duplication of a mutated oncogene allele would confer a growth advantage.¹⁹ Alternatively, aneuploidy (generated either spontaneously or by a carcinogen) could catalyze a chain reaction of genetic instability and therefore initiate carcinogenesis. Regardless of its precise role in oncogenesis, aneuploidy is clinically significant, because it may be a mechanism of acquired resistance to chemotherapy.¹⁹

Dysregulation of Cellular Proliferation

Mutations in proto-oncogenes and tumor-suppressor genes promote uncontrolled cellular growth if they lead to increased cellular proliferation, decreased apoptosis, or both.⁵ Cell proliferation is directly controlled by *cyclins*, a group of proteins that interact with *cyclin-dependent kinases* (CDKs) and are controlled by *cyclin-dependent kinase inhibitors* (CDKIs). Increased expression of cyclins and decreased activity (or loss) of CDKIs contribute to cell cycle dysregulation.

Cell proliferation is also controlled by *telomeres*, non-coding, tandemly repeated DNA sequences at the ends of chromosomes that allow DNA to be completely replicated all the way to the end of the coding sequence, thereby preventing enzymatic degradation and stabilizing the chromosome. A small amount of telomeric DNA is lost with cell cycle. Once this DNA reaches a critical point, a signal prevents further cell division.²⁰ *Telomerase* is a ribonucleoprotein enzyme complex (containing a reverse transcriptase subunit and an RNA subunit) that maintains telomere length and hence evades replicative senescence.^{5,20} In contrast to most somatic cells (which have no telomerase activity), many cancer cells have increased telomerase activity. Consequently, telomerase activity may be a marker of progression for a benign to malignant process and may be a therapeutic target.

There are multiple interconnected complex pathways of cell-cycle control. Noncoding ribonucleic acids (ncRNA) are functional RNA molecules that are not translated into proteins and are important mediators of these pathways. One such ncRNA is microRNA (miRNA), single-stranded, short (about 22-nucleotide) ncRNAs that are important

regulators of mRNA translation and degradation by binding at partially complementary sites in the untranslated regions of target mRNAs.²¹ miRNAs contribute to tumorigenesis by directly and indirectly (through epigenetic regulation) influencing translation of tumor-suppressor genes and oncogenes and by triggering a toll-like receptor-mediated tumorigenesis inflammatory response.²¹ miRNAs are in turn regulated by endogenous RNAs, which share miRNA response elements with mRNA, thereby vying for miRNA binding.^{22,23} As such, endogenous RNAs can remove the repressive effect of miRNAs on gene expression. The result is a complex network of classic genetic and epigenetic regulation of gene expression by miRNAs and endogenous RNAs. Dysfunctional endogenous RNAs can promote oncogenesis by removing the inhibitory effect of miRNA on oncogenes.^{22,23}

Cancer Stem Cells

Most cancers arise from a single cell that has undergone genetic mutations.²⁴ Such cells, known as *cancer stem cells*, have the ability to self-renew, proliferate, and produce the heterogeneous lineages of cancer cells within a tumor.²⁵ It is unclear whether cancer stem cells are true pluripotent stem cells, adult tissue-specific stem cells that acquire oncogenic mutations, or mature cells influenced by their microenvironment to undergo de-differentiation.² The process of tumor progression from cancer stem cells is also unclear. It may involve aberrant differentiation of cancer stem cells or it may involve cell-cell fusion between cancer stem cells and differentiated heterogeneous somatic cells, which can then undergo further cell division into various permutations of phenotypically unique cancer stem cells, mutated differentiated cells, or fused cells. Both pathways account for cellular heterogeneity and aneuploidy noted in tumors.²

There is growing evidence of lung cancer stem cells. Normal stem cells and lung cancer cells share several proliferative cell signaling pathways (e.g., K-ras, hedgehog, phosphate and tensin homolog [PTEN], Akt, and phosphoinositide 3-kinase [PI3K]).²⁶ Furthermore, lung cancers often share cell-surface markers with lung stem cells, which may explain the distribution of lung cancer histologies along the tracheal-bronchiole-alveoli axis.²⁶ For instance, squamous cell carcinomas, which tend to occur in the central airways, and stem cells of the pseudostratified epithelium of the central airways both contain keratin-expressing basal cells.²⁷

There is also growing evidence of esophageal cancer stem cells. Several studies on murine models demonstrated evidence of phenotypic stem-cell surface markers (e.g., α -6 integrin,²⁸ p75^{ntr},²⁹ and CD44³⁰). Based on evidence found in murine models, pluripotent bone marrow progenitor cells contribute to Barrett esophagus.³¹ Given the relative low turnover of lung and esophageal epithelial tissue compared with hematopoietic cells and keratinocytes, stem cells research in lung and esophageal basic science research has been somewhat limited.

The cancer stem cell theory has important therapeutic implications. The success of existing systemic chemotherapy relies on a stochastic model in which all cells in a tumor have the same oncogenic potential.³² However,

if there is only a small subset of cells with proliferative potential (i.e., cancer stem cells), treatment failure is likely. In fact, non-small-cell lung cancer (NSCLC) patients with CD133⁺ lung cancer stem cells are less responsive to platinum treatment.³³ Potential mechanisms for resistance of cancer stem cells to chemoradiation therapy include their relative dormant nature compared with nontumorigenic cancer cells (which tend to replicate more rapidly), ability to survive in hypoxic microenvironments, upregulation of chemotherapy efflux mechanisms, and upregulation of DNA repair pathways.^{32,34}

EPIGENETICS

In basic genetics, the expression of a gene (the *phenotype*) is directly associated with the DNA sequence of the gene (the *genotype*). However, this seemingly simple association between phenotype and genotype is often more complex. There are other heritable changes in gene expression not accompanied by alterations in the DNA sequence. These processes, known as *epigenetics*, provide insight into the complex link between the genotype and expressed phenotype, which may differ from the phenotype anticipated by basic genetics. Epigenetic changes may explain why cells in the human body share the same genome yet have vast (yet stable) differences in gene expression.³⁵

The most studied area of epigenetics is DNA methylation. DNA methylation occurs in normal cells, predominantly on cytosines, which are adjacent to guanines and separated by only a phosphodiester bond. This dinucleotide sequence (*CpG*, shorthand for 5' cytosine-phosphate-guanine) is distinct from cytosine-guanine DNA base pairing.³⁶ High-density *CpG* regions (known as *CpG islands*) span the promoter region of many (approximately 40%) genes and are often constitutively unmethylated in normal tissues.^{36,37} When these islands are methylated by DNA methyltransferases, transcription is repressed.³⁸ During the process of tumorigenesis and the resultant accumulation of genetic defects, there is a progressive loss of total genomic methylation, an increased frequency of hypermethylation at *CpG* islands, and an increase in histone modification.³⁶

One of the epigenetic hallmarks of cancer cells is global genomic hypomethylation compared with the methylation content in normal cells.^{39,40} Hypomethylation occurs at highly repeated, interspersed DNA sequences (which results in transcriptional interference of neighboring genes and cancer-associated gene insertions)^{41,42}; centromeric satellite DNA^{43,44}; and single-copy transcriptional control sequences.^{45,46} The contribution of DNA hypomethylation to tumorigenesis is independent of effects of DNA hypermethylation at *CpG* islands. It is neither a prelude nor a consequence of DNA hypermethylation.⁴⁷

The mechanistic basis for the contribution of hypomethylation to tumorigenesis is poorly understood but may include genomic instability (thereby facilitating genetic recombination) and dysfunctional transcriptional control elements (thereby increasing oncogene expression).⁴⁷

DNA hypermethylation in tumorigenesis usually affects the *CpG* islands at the promoter regions of tumor suppressor genes (upwards of 80% of patients with lung cancer) and transcription factors, which can upregulate expression of oncogenes or downregulate expression of tumor suppressor genes.^{48,49} Although it is less well understood, hypermethylation may also affect non-*CpG* island promoters and gene target sites.⁵⁰ In general, promoters with hypermethylated *CpG* islands cannot initiate transcription unless it is overridden by alternative signals (e.g., demethylation or chromatin modulation).⁵⁰ Consequently, epigenetic silencing of tumor-suppressor genes leads to upregulation of cell survival and proliferation pathways. In contrast to genetic mutations, which often affect proliferation pathways at a single foci,⁵¹ multiple epigenetic events can affect a single signaling pathway and in turn affect other pathways, thereby promoting tumorigenesis in a more integrated manner.⁵⁰

Histones, the major protein component of chromatin, also undergo epigenetic modification, predominately through changes in lysine acetylation (via histone acetyltransferases and deacetylases), arginine and lysine methylation (via histone methyltransferases), and serine phosphorylation (via histone kinases).³⁶ Such covalent modifications can alter the physical properties of chromatin, thereby influencing its interactions with catalytic enzymes and hence its control of gene activity.^{35,52} There are also noncovalent modifications that contribute to chromatin variation, including chromatin-remodeling complexes, variations in histone proteins, and nucleosome (segments of DNA wound around histone proteins) remodeling.^{35,50,53} Epigenetic chromatin modifiers such as the polycomb complexes of proteins, which are important for long-term transcriptional repression, may link epigenetic gene silencing with cancer stem cells.^{50,54}

DNA hypomethylation, DNA hypermethylation, histone modification, and likely undiscovered epigenetic pathways are not mutually exclusive. There is significant functional crosstalk among these pathways, producing an intricate network of signals that influence gene expression.⁵⁵⁻⁵⁸ Epigenetic changes in cancer may serve as biomarkers and potential therapeutic targets.

PROTEOMICS

As a result of posttranslational modifications, genomic studies of DNA and RNA often poorly correlate with protein expression and hence the phenotype of the cell or tissue.⁵⁹ The *proteome* is the protein complement of the genome. Hence, *proteomics* is the study of the structure and function of proteins expressed by the genome of a biological system.⁶⁰ Because of posttranslational modifications and the resultant heterogeneous nature of proteins, human proteomics is more complex than human genomics.

Most proteomic approaches involve homogenization of a particular sample of interest followed by separation of the proteins in the sample of two-dimensional polyacrylamide gel electrophoresis (2D-PAGE).^{60,61} The samples are first separated by their isoelectric point and then by their molecular weight (hence, "2D" PAGE).

The proteins on these gels are displayed as spots, which can be identified by Western blot analysis and comparing the results with protein databases or by digesting the gel spots with trypsin and then performing mass spectrometry on the sample.⁵⁹ Alternative techniques to 2D-PAGE include high-performance liquid chromatography and gel-free isotope-labeling techniques to separate peptides from a sample.⁵⁹

Regardless of the separation technique, mass spectrometry is the primary technique used in proteomics to identify proteins and peptides in a sample. Protein identification is based on measurement of their molecular weight and charge (m/z ratio). To obtain these measurements, samples are ionized (i.e., by matrix-assisted laser desorption ionization or by electrospray ionization), travel through a mass analyzer that separates ions based on their m/z ratio (e.g., using time-of-flight, Fourier transformation, or ion traps), and then are processed by a mass detector.^{59,60,62,63} A second mass spectrometer can be added to this sequence (known as *tandem mass spectrometry*) to identify the amino acid sequence of a peptide. The resultant data are compared against protein databases to identify the protein in the sample.^{59,60} As an alternative to performing proteomic analysis in two steps, multidimensional protein identification technology uses high-performance liquid chromatography in-line with tandem mass spectrometry.⁶⁴

Understanding the proteome will provide tremendous insight into the downstream cellular response to perturbations in the genome of thoracic malignancies.

METABOLOMICS

Metabolomics is the quantitative description of all endogenous metabolites in a biological sample (e.g., tissue, blood, urine) simultaneously.^{65,66} It allows for a global assessment of changes in phenotype in the context of the immediate environment of the cell by reflecting changes in enzymatic gene regulation and altered kinetics of metabolic enzymes.⁶⁵ Metabolites include those involved in cellular respiration (e.g., metabolic intermediates of glycolysis, anaerobic metabolism, the citric acid cycle), amino acid metabolism (i.e., alterations in the levels of essential and nonessential fatty acids and their metabolites), fatty acid metabolism (i.e., the relative abundance of unsaturated and saturated fatty acids), and nucleotide metabolism.^{66,67} Most metabolomic platforms are based on spectroscopic techniques (e.g., nuclear magnetic resonance and mass spectroscopy).⁶⁶ Multivariate metabolomic analyses are performed in three major steps. First, pattern recognition (also known as *group clustering*) is used to decipher differences in spectral patterns between two groups (e.g., cancer and normal specimens). Next, the spectral region of interest identified in the first step of the analysis is linked to a specific metabolite based on its nuclear magnetic resonance chemical shift. The final step involves ascertaining associations between the metabolite of interest and a particular clinical outcome.⁶⁵ Although studies on cancer metabolomics are still in the preclinical exploratory phase, metabolomics have a potential role in cancer diagnosis and assessment of response to therapy by providing relatively inexpensive,

rapid, and automated methods to assay biomarkers in biological samples.⁶⁵⁻⁶⁷

CLINICAL APPLICATION OF NUCLEIC ACID AND PROTEIN BIOMARKERS

A *biomarker* is a surrogate indicator of a biological process that can be measured qualitatively or quantitatively. DNA biomarkers include mutations (in oncogenes, tumor-suppressor genes, and mismatch repair genes), single nucleotide polymorphisms, DNA copy number changes, chromosomal translocations, microsatellite instability, and epigenetic changes (e.g., differential promoter methylation). RNA biomarkers include messenger RNA (mRNA) and miRNA. Protein biomarkers include proteins that are expressed on cell surfaces or shed into serum. For patients with thoracic malignancies, nucleic acid and protein biomarkers may have diagnostic, prognostic, and predictive roles in patient care and may serve as therapeutic targets.

In general, detection of nucleic acid and protein biomarkers in tumor tissue primarily has prognostic, predictive, and therapeutic implications. In contrast, detection of these biomarkers in other tissues and body fluids primarily has diagnostic implications for cancer screening and for detection of occult malignancy.

Detection in Tumor Tissue

Lung Cancer

p53. p53 is a tumor-suppressor gene that plays a central role in cell-cycle regulation, apoptosis, and DNA repair. As such, inactivation of (or mutations in) p53 lead to derangements in cell-cycle progression, evasion of apoptosis, and genomic instability due to impaired DNA repair mechanisms. Given its vital role in controlling cellular proliferation, it is not surprising that p53 mutations are among the most common mutations in all human malignancies.⁶⁸ As much as 50% of NSCLCs and 90% of small-cell lung cancers contain p53 mutations or deletions.^{68,69} A systematic review of 56 studies found that p53 mutations in NSCLC are associated with worse overall survival for all stages and for both adenocarcinoma and squamous cell carcinoma histologies. In that study, there were insufficient data to determine the prognostic significance of p53 mutations in small-cell lung cancer.⁷⁰

ERCC1. Platinum-based chemotherapy is the gold standard for neoadjuvant and adjuvant chemotherapy for patients with resectable NSCLC and for treating patients with unresectable NSCLC.⁷¹⁻⁷³ The mechanism of action of platinum chemotherapeutic agents (i.e., cisplatin, carboplatin, and oxaliplatin) is formation of DNA adducts.^{74,75} These adducts disrupt DNA replication.

Excision repair cross-complementing group 1 (ERCC1) is part of a DNA repair pathway that recognizes and removes platinum-induced DNA adducts, therefore conferring resistance to platinum-based chemotherapy.⁶⁸ ERCC1 expression is common (present in

44% of tumors in one study⁷⁶) and is an important prognostic factor (independent of treatment). Low ERCC1 levels are associated with a worse prognosis and identify patients who may benefit from platinum-based chemotherapy.⁷⁷ In contrast, high ERCC1 levels are associated with a better prognosis and identify patients who are less likely to benefit from platinum-based chemotherapy.^{76,78} One possible explanation is that high levels of ERCC1 indicate intact DNA repair pathways and hence greater genomic stability.⁷⁸ In one study of 51 NSCLC patients who underwent resection for cure, high-level ERCC1 expression was associated with an absolute improvement in median overall survival of 60 months.⁷⁸

***k-ras*.** The *k-ras* gene encodes a G protein involved in signal transductions in cellular growth, differentiation, and apoptosis. Among patients with NSCLC, mutations in *k-ras* are more common in white smokers (26%), as compared with nonsmokers (6%). It is also more common in adenocarcinoma (30%), as compared with squamous cell carcinoma (5%).⁷⁹⁻⁸² It is important to note that *k-ras* mutations are mutually exclusive of *EGFR* mutations. Consequently, patients with *k-ras* mutations may be intrinsically resistant to *EGFR*-targeted therapies.⁸³

The gold standard for detecting *k-ras* mutations is DNA sequencing.⁸⁴ Currently, there is no effective therapy specifically targeting *k-ras* mutations; promising small-molecule inhibitors are under preclinical investigation.

Epidermal Growth Factor Receptor. Epidermal growth factor receptor is a member of the human *EGFR* (HER) family of transmembrane tyrosine kinase receptors that promotes cellular proliferation, impairs apoptosis, and increases angiogenesis.^{68,84} *EGFR* overexpression and mutations are rare in small-cell lung cancer.⁶⁸ In contrast, *EGFR* overexpression is seen in as much as 80% of NSCLCs.⁸⁵ *EGFR* mutations occur in as much as 22% of NSCLCs and are most common among women, patients of East Asian descent, nonsmokers, and patients with adenocarcinomas.^{84,85} It has important therapeutic implications because select NSCLC patients with *EGFR* mutations have a survival benefit when treated with *EGFR* tyrosine kinase inhibitors.

EML4-ALK. Anaplastic lymphoma kinase (ALK) is a receptor tyrosine kinase. As such, it plays a role in cellular signal transduction.^{86,87} In approximately 3% to 13% of NSCLC patients, the 5' end of echinoderm microtubule-associated protein-like 4 (EML4) gene binds with the 3' end of the ALK gene, resulting in a fusion oncogene (EML4-ALK) that tends to occur in younger patients, women, light or never-smokers, and adenocarcinomas (specifically those with acinar histologies).⁸⁸ EML4-ALK results in constitutive activity of ALK that results in downstream activation of several signaling pathways important in cellular proliferation (e.g., Ras, JAK3-STAT3, PI3K), inhibition of apoptosis, and cell migration.⁸⁶ The EML4-ALK oncogene has therapeutic implications; crizotinib is a TKI that targets it. It is important to note that EML4-ALK mutations are mutually exclusive with *k-ras* and *EGFR* mutations.

Vascular Endothelial Growth Factor. Vascular endothelial growth factor (VEGF) binds to a group of receptor tyrosine kinases (VEGF receptors) that stimulate angiogenesis. VEGF expression in NSCLC is associated with a worse overall survival rate.⁸⁹ In one study of resectable NSCLC, VEGF expression was associated with a sevenfold increased risk of all-cause mortality.⁹⁰ VEGF also has therapeutic implications; bevacizumab is a monoclonal antibody against VEGF that is effective in select patients with NSCLC.

Tumor Panels. Lung cancer, like all thoracic malignancies, cannot be fully characterized by a single biomarker. Each tumor has its own unique "molecular fingerprint." As such, tumor marker panels may be more useful rather than detection of a single tumor biomarker. D'Amico and colleagues examined the tumors of 408 stage I NSCLC patients. They identified five biomarkers by immunohistochemistry (IHC) that were associated with the risk of recurrence and death. Each marker was associated with a different oncogenic pathway: apoptosis (p53), angiogenesis (factor VIII), growth regulation (erb-b2), cell adhesion (CD-44), and cell cycle regulation (Rb).⁹¹ Using this model, patients were substratified by survival rates: zero to one marker (5-year survival, 77%), two markers (5-year survival, 62%), and three to five markers (5-year survival, 62%).

Microarray Analysis. Oncogenesis and metastasis are largely controlled at the level of transcription. Consequently, significant insight can be gained by globally assessing gene expression. The workhorse for such analyses is DNA microarray. A DNA microarray comprises multiple, gene-specific polynucleotides (probes) arranged along exact coordinates of a two-dimensional grid (array).⁹² Total RNA from experimental and reference specimens is reverse-transcribed to fluorescence-labeled complementary DNA (cDNA) before incubation with the microarray. This process allows for simultaneous quantification of the relative (experimental vs. reference) amount of mRNA transcripts. The number of immobilized microarray probes, which may number in the hundreds of thousands, is reflective of the relative degree of gene expression. This method depends on the highly sensitive and specific hybridization between complementary strands of nucleic acids.

Data analysis revolves around four common themes: detection of differential gene expression, pattern discovery, prediction of specimen characteristics, and inference of molecular pathways and networks. Microarray studies generate a vast amount of data, which is one of the major challenges of this technology.

A number of microarray studies have used differential gene expression to predict survival and identify potential novel therapeutic targets.⁹³⁻⁹⁵ Beer and colleagues examined 86 early-stage adenocarcinomas and constructed a 50-gene risk index based on hierarchical clustering.⁹⁵ Members of this 50-gene set included genes that had not been previously associated with survival, suggesting potential novel therapeutic targets. Using this gene set, the investigators were able to predict survival.

Other microarray studies have used pattern discovery to segregate NSCLC histologies based on gene

expression profiles. Bhattacharjee and colleagues⁹⁶ studied 186 NSCLC tumors. They used a specialized clustering technique for pattern discovery to identify four distinct adenocarcinoma subgroups based on gene expression profiles.

To date, there have been numerous studies that have expanded on the potential prognostic significance of miRNAs in NSCLC tissue. Raponi and colleagues⁹⁷ reported the robust predictive ability of miRNA-146b in the overall survival in squamous cell carcinoma. Landi and colleagues⁹⁸ identified another miRNA expression profile that strongly differentiated 165 adenocarcinomas from 125 squamous cell carcinomas based on decreased expression of miRNAs let-7e and miR-34a, -34c-5p, -25, and -191. This panel was associated with worse survival among male smokers with stages I to IIIA squamous cell carcinoma.⁹⁸

In addition to the prognostic significance of miRNA in tumor tissue, miRNAs from the adjacent nontumor microenvironment have been investigated with interesting results. Boeri and colleagues⁹⁹ have explored miRNA expression profiles of lung tumors and normal lung tissues and noted that miRNA expression patterns significantly distinguished tumors from normal lung tissues, tumor histology and growth rate, and clinical outcome. These findings strengthen the growing evidence that the normal lung microenvironment potentially influences tumor growth and proliferation.

Finally, microarray studies have also shown promise as a potential indicator of risk of lymph node metastasis and responsiveness to chemotherapy. Kikuchi and colleagues microdissected individual cancer cells from 37 NSCLC tumors before performing microarray analysis to identify novel genes involved in oncogenesis, using a clustering algorithm to distinguish adenocarcinomas from squamous cell carcinomas. A separate analysis of the 18 adenocarcinomas identified 40 genes whose expression profiles could reliably distinguish tumors with lymph node metastasis from those tumors without metastasis. Finally, they were able to predict chemosensitivity based on expression profiles.¹⁰⁰ This study highlights the potential utility of gene-expression profiles of NSCLC patients to guide personalized cancer therapy.

Proteomic Analysis. Proteomic analysis of lung cancer specimens has demonstrated the utility of protein signatures in the diagnosis and histologic classification of lung cancer.¹⁰¹⁻¹⁰³ Protein signatures also have potential prognostic significance. Yanagisawa and colleagues¹⁰⁴ examined the protein signatures in stage I NSCLC patients and internally validated a 25-protein signature panel. A high-risk signature was identified that was significantly predictive of overall and relapse-free survival. These studies highlight the potential role of proteomics in counseling patients and identifying those patients at high risk for recurrence, which could be used to guide therapy.

Esophageal Cancer

Her2. Her2/neu (also known as ErbB2) is a receptor tyrosine kinase that inhibits apoptosis and promotes cellular proliferation through PI3K pathways.¹⁰⁵ In

adenocarcinomas, Her2/neu is overexpressed in 10% to 80% of tumor specimens, and gene amplification is found in 15% to 100%.^{105,106} Her2/neu overexpression is associated with depth of invasion, lymph node metastases, distant metastases, and poor prognosis.^{105,107,108} As compared with adenocarcinomas, Her2/neu overexpression (0%-56% of tumors) and gene amplification (0%-25% of tumors) is lower in squamous cell carcinomas.^{105,109} Although Her2/neu overexpression may also be associated with stage and prognosis in squamous cell carcinomas, its independent prognostic value is controversial.¹⁰⁵ Her2/neu expression has important therapeutic implications because of the availability of a humanized monoclonal antibody (trastuzumab).

VEGF. As with lung cancer patients, VEGF expression has significant prognostic and therapeutic implications for esophageal cancer patients. Based on a recent meta-analysis, high VEGF expression in esophageal cancer is associated with a nearly twofold increase in the risk of death.¹¹⁰ Bevacizumab is a monoclonal antibody that binds to VEGF, thereby impairing its ability to activate the VEGF receptor.

Microarray Analysis. Microarray studies on esophageal tumors have also provided insight into its potential role in treating patients with esophageal cancer. Microarrays are able to distinguish between tissues at various stages of disease progression. Zhou and colleagues were able to identify differential expression of genes in normal esophageal mucosa, basal cell hyperplasia, high-grade dysplasia, carcinoma in situ, and overt cancer.¹¹¹ Microarray studies have also led to the discovery of gene expression profiles that can also distinguish between Barrett esophagus and adenocarcinoma^{112,113} and between adenocarcinoma and squamous cell carcinoma.¹¹¹ In addition, these analyses demonstrated the prognostic importance of gene expression profiles in esophageal cancer patients who have undergone surgical resection. In one such study of 64 esophagectomy patients, Luketich and colleagues demonstrated the ability to prospectively place patients in high-risk and low-risk groups according to their tumor's genetic signature. In their multivariate analysis, only the gene signature was independently associated with survival.¹¹⁴

Microarray analyses have also led to the identification of novel oncogenic genes that improves our understanding of oncogenesis and treatment of esophageal cancer. Zhou and colleagues¹¹¹ identified a gene (*PI60ROCK*, a rho-associated serine/threonine kinase isoenzyme that regulates cell motility and morphologic changes) that plays an important role in carcinogenesis. This gene was dramatically upregulated in tissues with high-grade dysplasia compared with normal tissues. As such, its activation is likely one of the early events in esophageal carcinogenesis and may be a potential therapeutic target.

Finally, microarray analysis can be used to predict response to therapy. In a study of 20 resected esophageal tumors in patients who underwent adjuvant therapy, Kihara and colleagues¹¹⁵ identified a 52-gene profile that accurately predicted prognosis and chemosensitivity and chemoresistance to various agents. Prospective studies

validating these gene sets and predictive models have not been performed.

Mesothelioma

Microarray Analyses. Because malignant pleural mesothelioma (MPM) is a relatively rare tumor, few studies have evaluated the use of microarrays in patients with mesothelioma. Similar to microarray analyses of other malignancies, studies on MPM have unfolded mechanisms of oncogenesis and tumor dissemination. Hoang and colleagues noted overexpression of matriptase (a membrane protease involved in the activation of other proteases, tumor invasion, and metastases).¹¹⁶

Similar to other malignancies, microarrays provide prognostic information for MPM patients. Researchers at Brigham and Women's Hospital examined specimens from 17 MPM patients with different overall survival times to identify a four-gene expression ratio test that reliably predicted treatment-related outcomes, independent of histologic subtype.¹¹⁷

Detection in Lymph Node Tissue

Lung Cancer

Regional lymph node metastasis assessed by routine histologic analysis is associated with a marked decreased survival rate compared with node-negative disease.¹¹⁸ However, even with completely resected node-negative T1 or T2 tumors, 5-year cancer-specific survival rates are only 60% to 90%, possibly owing to undetected occult micrometastases.^{119,120} Two techniques are primarily used to detect occult micrometastases: IHC and reverse-transcriptase polymerase chain reaction (RT-PCR). Both techniques rely on the identification of an appropriate tumor marker.

Cancer and Leukemia Group B (CALGB) 9761 was a prospective, multi-institutional study that assessed the prognostic implications of occult mediastinal lymph node metastasis in patients who underwent curative resections of early stage (T1-2N0M0) NSCLC. As part of the study, IHC against cytokeratin (AE1/3, an epithelial tumor marker) was assessed in mediastinal lymph nodes.¹²¹ In the first 193 patients in the study, cytokeratin IHC upstaged 11% of patients to N2 disease.¹²¹ Use of IHC to detect occult micrometastases has two main drawbacks: (1) the need for visual detection (and hence the risk of human error), and (2) the inability to test the entire nodal specimen. RT-PCR overcomes these shortcomings.

Based on a number of RT-PCR-based studies, carcinoembryonic antigen (CEA, an embryonic epithelial surface glycoprotein) is another potentially suitable NSCLC tumor marker.¹²²⁻¹²⁴ Collectively, those studies demonstrated that CEA has a relatively high sensitivity (it can detect 1 malignant cell in as many as 10⁶ normal cells) and high specificity (because it is detected in almost all epithelial cells but not in nonepithelial cells). Consequently, detection of CEA (an epithelial protein) in mediastinal lymph nodes (which derive from embryonic mesenchymal tissue) is a sensitive and specific marker of occult metastases. CALGB 9761 used standard RT-PCR

for CEA; 43% of patients were upstaged based on RT-PCR analysis of mediastinal lymph nodes.¹²⁵

A potential shortcoming of occult micrometastasis detection by IHC and standard RT-PCR is the binary (yes/no) result regarding the presence or absence of occult metastases. In fact, the amount of micrometastatic burden may be important. Quantitative real-time RT-PCR (QRT-PCR) is a possible solution to this problem.

QRT-PCR uses a target molecule-specific oligonucleotide probe (e.g., CEA mRNA) with a covalently attached fluorescent reporter and quencher dye. If the target module of interest is present, the oligonucleotide probe will anneal to it. During the PCR extension phase, the fluorescent probe is cleaved by the exonuclease activity of Taq DNA polymerase, thus increasing the reporter dye's emission. Curves plotting the relative fluorescence change against the PCR cycle number are constructed, and the point of increase in fluorescence above the background (the threshold cycle [C_T]) is calculated. Because C_T values decrease linearly with increasing target molecule quantity, they provide a quantitative measurement.

QRT-PCR for CEA from samples from 53 patients enrolled in CALGB 9761 demonstrated the feasibility of QRT-PCR to detect occult micrometastases. This resulted in an estimated median of 7190 tumor cells per lymph node harboring occult micrometastases.¹²⁵ Several retrospective studies confirmed these findings and suggested a prognostic relationship between occult metastases detected by QRT-PCR for CEA.^{126,127} The prognostic importance of occult metastases in NSCLC patients awaits the final analysis of CALGB 9761, which is currently being finalized.

In addition to CEA, there are many other tumor markers (e.g., cytokeratin 7, cytokeratin 19, apomucin 1, KS1/4, LUNX, and PDEF).¹²⁸⁻¹³¹ KS1/4 is especially intriguing because it has very high specificity for lung cancer, and it is recognized by the monoclonal antibody Ber-EP4.¹³¹ Furthermore, there are monoclonal antibodies to Ber-EP4 (e.g., edrecolomab), which may be a therapeutic target. Its utility in treating lung cancer is yet to be determined.

Esophageal Cancer

Lymph node involvement is a strong predictor of recurrence and poor survival rates in esophageal cancer patients.¹¹⁸ Similar to studies evaluating the prognostic importance of IHC-detected NSCLC micrometastases, studies on esophageal cancer have produced mixed results, underscoring one of the potential pitfalls of IHC: sampling error because only a limited number of lymph node sections are examined.¹³²⁻¹³⁶

Luketich and colleagues used QRT-PCR to detect occult micrometastases in 387 lymph nodes from 30 histologically node-negative esophageal adenocarcinoma cancer patients.¹³⁷ Based on CEA expression, 11 patients were found to have occult metastases. Of those 11 patients, 9 developed recurrent disease. Kaplan-Meier analysis demonstrated that QRT-PCR-positive lymph nodes correlated with significantly lower disease-free and

overall survival rates.¹³⁷ These studies highlight the potential role of using QRT-PCR to identify patients with a high risk of recurrence to guide use of adjuvant chemotherapy.

Detection in Blood

Use of genetic science to detect circulating tumor cells (CTCs) in peripheral blood has a potential role in cancer screening, risk stratification, assessing response to therapy, and individualizing treatment. Because peripheral blood acquisition is safe and easily accessible, this approach is appealing. However, there are several challenges. First, a sensitive and specific marker needs to be identified. Second, one CTC must be detected among 10⁶ background circulating tumor cells. Consequently, most approaches use an enrichment step from peripheral blood followed by RT-PCR. Nonetheless, there can be significant signal-to-noise ratio, making it difficult to differentiate meaningful information from background gene expression.

Lung Cancer

Nucleic Acids. Although CTCs are detectable in patients with early-stage NSCLC, detection is more frequent in patients with advanced disease.¹³⁸ Several investigators have used RT-PCR to detect circulating tumor cells in patients with NSCLC. Such assays focused on a limited number of mRNA tumor markers, such as EGFR¹³⁹ and CEA.¹²⁴ These studies highlighted several important findings: (1) There is a clear correlation between a positive preoperative blood test and a postoperative pathological stage; (2) A significant number of patients with “early” stage NSCLC (based on radiographic studies and routine histologic analysis of tumor and lymph nodes) developed recurrent disease after surgery; and (3) There was a correlation between persistently positive postoperative blood samples and stage, suggesting occult systemic disease.

Several investigators have attempted to evaluate circulating miRNAs as a biomarker for cancer detection. In 2008, Mitchell and colleagues were the first to demonstrate that clinical samples of plasma and serum had measurable amounts of miRNAs and existed in a stable form through repeated freeze-thaw cycles.¹⁴⁰ Further investigation has validated that circulating miRNAs hold promise as diagnostic and prognostic biomarkers; many studies have demonstrated an association between circulating miRNAs and stage and survival. Not surprisingly, most of the studies on individual miRNA expression and miRNA panels have had inconsistent results, likely because of selection bias and lack of data normalization methods. The lack of a reliable housekeeping miRNA in serum to compare against is one such issue that complicates the significance of these studies.¹⁴¹

Because no single tumor marker will provide adequate sensitivity, tumor marker combinations may be preferable.¹⁴² Although these studies are promising, there are no prospective studies that have validated the prognostic implication of using nucleic acid tumor markers to detect CTCs.

Proteins. For several years, there has been interest in identifying peptide, protein, and autoantibody tumor biomarkers.¹⁴³⁻¹⁴⁶ Efforts to detect serum autoantibodies appear to be most promising. Abnormally expressed or structurally altered proteins may elicit the production of autoantibodies. A number of studies have demonstrated the feasibility of detecting such antibodies¹⁴⁷⁻¹⁴⁹ and serve as the basis for the development of biochips that provide molecular profiles of the antibody response to tumor antigens.¹⁵⁰

Esophageal Cancer

The presence of CTCs has important prognostic implications. For patients with metastatic esophageal cancer, two or more CTCs (per 7.5 mL of peripheral blood) is associated with lower progression-free¹⁵¹ and overall survival rates.^{151,152} The presence of CTCs also has important therapeutic implications, because it is associated with lower response rates to chemotherapy¹⁵¹ and lower response to radiotherapy.¹⁵³

Detection in Bone Marrow

Lung Cancer

Using IHC, several groups have demonstrated a 22% to 59% incidence of bone marrow micrometastases in NSCLC patients, which have potential prognostic implications.¹⁵⁴⁻¹⁵⁸

Detection in Sputum

Lung Cancer

Sputum analysis for the early detection of lung cancer has been studied for decades. In the 1980s, several lung cancer screening trials examined the role of sputum cytology and chest radiographs in the early diagnosis of lung cancer, which demonstrated that standard sputum cytology has a relatively low sensitivity for detecting lung cancers.¹⁵⁹⁻¹⁶¹ Still, sputum specimens are readily accessible from patients, making sputum cytology an appealing method for lung cancer screening and surveillance. Consequently, there has been growing interest since those initial screening trials in using molecular techniques to augment the sensitivity of sputum analysis.

There is a relatively low amount of tumor DNA (about 1%) in a background of normal DNA.¹⁶² As such, crude DNA and RNA (analyzed through gene sequencing or mutation-specific oligonucleotide hybridization) has no utility in lung cancer screening.¹⁶² However, PCR mutation analysis of p53,¹⁶³ *k-ras*,¹⁶⁴ EGFR,¹⁶⁵ EML4-ALK,¹⁶⁶ and other markers may be helpful. Other potential biomarkers include heterogeneous nuclear riboprotein A2/B1,¹⁶⁷ hypermethylated promoters,¹⁶⁸ and microRNA.¹⁶⁹ Given the heterogeneous nature of lung cancer and the absence of a tumor marker with 100% sensitivity, tumor marker panels are likely needed for lung cancer screening. Such panels may be especially useful as an adjunct to low-dose computed tomography screening programs.

NEXT-GENERATION DNA SEQUENCING IN CLINICAL CARE

For nearly 30 years, the most common method of DNA sequencing was the capillary electrophoresis–based Sanger (chain termination) method.¹⁷⁰ This method involves the denaturation of DNA into two strands. DNA replication is then performed in vitro with polymerase and nucleotides that have been chemically altered. Once the altered nucleotides are incorporated into the DNA sequence that is being replicated, DNA replication is terminated. This process is performed for each of the four nucleotides, thereby generating strands of DNA of various lengths, which are overlaid with one another to decipher the code. Recently, the Sanger technique has been largely supplanted by next-generation (also known as second-generation) sequencing.

Similar to Sanger-based methods, next-generation sequencing methods entail the sequential detection of nucleotides from signals emitted from fragments of DNA as they are being replicated from a template DNA strand. In contrast to Sanger methods, however, this process occurs in a digital, massively parallel fashion, enabling higher throughput DNA sequencing at a fraction of the cost per base. Currently available next-generation platforms include Illumina, Helicos, 454 Pyrosequencing, SOLiD, and Ion Torrent. Next-generation sequencing includes a number of whole-exome (sequences of exons, the DNA sequences that encode proteins), whole-transcriptome (the sequence of expressed genes), whole-genome, epigenome, and location-based approaches (which map the location of nucleic acid–nucleic acid and nucleic acid–protein interactions).^{171–173} It has allowed cancer genetics to move from focused approaches (e.g., single-gene sequencing) to more comprehensive approaches.¹⁷² The “depth” of a sequencing process refers to the number of times a single nucleotide is read, hence the terms *deep* and *ultra-deep sequencing*. Next-generation methods allow a much greater depth (also known as *coverage*) of sequencing, thereby allowing sequencing to be performed with greater sensitivity and to provide a more unbiased assessment of the heterogeneity of specimens. As described earlier in this chapter, tumors are a heterogeneous group of cells.

Next-generation techniques have a number of potential roles in oncology, including cancer gene discovery, chromosomal rearrangement discovery, characterization of clonal and subclonal cell populations in tumors, and integrated biomarker analysis to longitudinally track adoptive changes in signaling pathways during the course of treatment.^{174–176} For instance, next-generation sequencing could be used to track circulating tumor markers during the course of treatment and screen for adoptive changes by the tumor, thereby facilitating appropriate treatment changes to be made during the course of therapy. As such, next-generation sequencing has tremendous potential in personalized oncology as it becomes more widely available. The human genome project took more than 12 years to complete and cost \$2.7 billion. With next-generation sequencing, the entire genome of an individual can be sequenced in less than a week for

\$5000 to \$10,000. As the cost of these techniques continue to decline, next-generation sequencing will likely emerge into the clinical care of cancer patients.¹⁷¹

PERSONALIZED ONCOLOGY

Even histologically similar tumors are heterogeneous diseases—no two tumors and their biological milieu are the same. As such, a “one-size-fits-all” approach to oncology is fraught with frequent treatment failures. As our understanding of the molecular biology of thoracic malignancies continues to evolve and becomes increasingly more sophisticated, personalized oncology is becoming a reality. Many techniques (e.g., assessment of differential gene expression profiles, protein expression profiles, and detection of occult metastasis) are promising but are largely unproven and have not been introduced into mainstream clinical care. Other techniques (e.g., detection of gene overexpression and gene mutations) are being actively used in practice and have led to rational use of targeted therapies (Table 45-1). The use of molecular diagnostics to risk-stratify patients (and hence guide therapy), as well as the use of targeted therapies, has developed furthest in the treatment of NSCLC.

Customized Chemotherapy

For instance, ERCC1 overexpression is associated with poor response to platinum-based chemotherapy. Furthermore, ERCC1-negative tumors are associated with lower survival rates.⁷⁶ As such, adjuvant cisplatin-based chemotherapy may benefit patients with ERCC1-negative tumors.⁶⁸ Currently, there are several clinical trials exploring the use of personalized chemotherapy based on ERCC1 status, including adjuvant therapy for resected stage I NSCLC (NCT00792701), adjuvant therapy for resected stage II to III (non-N2) NSCLC (NCT00775385), and therapy for advanced (stage IIIB [malignant effusion] and IV) NSCLC (NCT00499109).

In a recent landmark trial, the BATTLE (Biomarker-Integrated Approaches of Targeted Therapy for Lung Cancer Elimination) trial enrolled 255 patients with chemorefractory stage IV NSCLC and used molecular biomarkers analyzed in real-time core biopsies to adaptively randomize patients to one of four treatment arms (erlotinib, vandetanib, erlotinib plus bexarotene, or sorafenib) based on their molecular profile.¹⁷⁷ At eight weeks, there was a 46% control rate, establishing a potential new paradigm in NSCLC treatment.

Targeted Therapies

Targeted therapies are largely limited to patients with advanced (stage IIIB and IV) disease. In particular, all patients with advanced disease should be tested for EGFR and ALK mutations. For patients with nonsquamous stage IIIB and IV NSCLC and EGFR mutations, use of tyrosine kinase inhibitors (i.e., erlotinib, gefitinib, and afatinib) has a significantly improved overall survival (median, 6.7 months vs. 4.7 months; $P < 0.001$),¹⁷⁸ progression-free survival (median, 10.8 months vs. 5.4

TABLE 45-1 Selected Non–Small-Cell Lung Cancer Oncogenes and Targeted Therapy

Oncogene Alteration	Incidence (%)	Clinical Relevance	Treatment
<i>BRAF</i> Mutation	1-5	V600E mutation: most common, equal association with smokers and nonsmokers May be mechanism of acquired EGFR TKI resistance	V600E mutation: dabrafenib vemurafenib
<i>EGFR (ErbB1, HER1)</i> Mutation	13-50	Exon 19 deletion and Exon 21 point mutation are the most common Predominately adenocarcinoma and nonsmokers Up to 50% frequency in Asian	TKI: gefitinib, erlotinib Monoclonal antibodies: cetuximab
<i>EML4-ALK</i> Fusion	3-13	Most frequent in adenocarcinomas, nonsmokers, men, and younger patients	Nonspecific TKI: crizotinib Monoclonal antibodies: trastuzumab
<i>Her2/neu (ErbB2)</i> Mutation	2-6	Mostly adenocarcinomas and nonsmokers	
Amplification	23	Mechanism of resistance to EGFR TKI	
<i>KRAS</i> Mutation	5-30	Mostly adenocarcinomas and smokers May contribute to resistance to ALF, BRAF, and PI3K inhibitors	No approved therapy Small-molecule inhibitors in preclinical trials Nonspecific TKI: crizotinib
<i>MET</i> Mutation	<5		
Amplification	21	Mechanism of resistance to EGFR TKI	
<i>PIK3CA</i> Mutation	<10	Frequently occurs in association with other mutations; more common in squamous cell	Nonspecific TKI: crizotinib
Amplification	5-43	Mechanism of resistance to EGFR TKI	
<i>PTEN</i> Mutation	1.7-10	Associated with PI3K activation, resistance to EGFR TKI, and sensitivity to PI3K inhibitors	Nonspecific TKI: crizotinib
Loss of function	4-21	More frequent in squamous cell Associated with PI3K activation, resistance to EGFR TKI, and sensitivity to PI3K inhibitors	
<i>RET</i> fusion gene	1-2	More frequent in squamous cell Mostly adenocarcinomas and nonsmokers	RET inhibitors: cabozantinib
<i>ROS1</i> fusion gene	2	Mostly adenocarcinomas, nonsmokers, and younger patients	ALK inhibitor: crizotinib
<i>VEGF</i>			Monoclonal antibodies: bevacizumab VEGFR TKI

BRAF, v-raf murine sarcoma viral oncogene homolog B1; *EGFR*, epidermal growth factor receptor; *EML4-ALK*, echinoderm microtubule-associated protein-like 4 anaplastic lymphoma kinase; *ERBB*, avian erythroblastosis oncogene B; *Her2*, human epidermal growth factor receptor 2; *KRAS*, Kirsten Rat sarcoma viral oncogene homolog; *MET*, mesenchymal-epithelial transition; *PIK3CA*, phosphoinositide-3-kinase catalytic alpha polypeptide; *PTEH*, phosphatase and tensin homolog; *RET*, rearranged during transfection; *ROS1*, reactive oxygen species 1; *TKI*, tyrosine kinase inhibitor; *VEGF*, vascular endothelial growth factor; *VEGFR*, vascular endothelial growth factor receptor.

Data from references 79-82, 84, 85, 88, and 186.

months; $P < 0.001$),¹⁷⁹ and objective response rates (73.7% vs. 30.7%; $P < 0.001$)¹⁷⁹ compared with placebo. Unfortunately, long-term results with TKIs are disappointing. Most tumors develop resistance to TKIs¹⁸⁰ because of crosstalk between signaling pathways and rewiring of feedback loops.¹⁷⁵ This highlights the need to target cancer cells at multiple cellular growth and proliferation pathways.

Cetuximab is a monoclonal antibody that targets the extracellular domain of EGFR and is an alternative to oral TKIs. However, for patients with advanced NSCLC, the addition of cetuximab offers only a slight increase in overall survival (11.3 months vs. 10.1 months; $P = 0.044$),

is harder to administer, and is associated with high rates of toxicities.¹⁸¹

For patients with EML4-ALK mutations, there is no benefit to treatment with TKIs because ALK mutations are mutually exclusive with EGFR mutations.¹⁸² However, for patients with EML4-ALK, crizotinib (an ALK inhibitor) has a potential benefit. Based on preliminary data of a phase 1 trial, the overall response rate was 57%, and 33% had stable disease at a median follow-up of 6.4 months.¹⁸³ A phase 3 trial is underway.

Other potential therapeutic targets have been identified. Targetable oncogenes in adenocarcinomas include tyrosine kinase inhibitors toward BRAF mutations,

HER2 insertions, MET mutations, PIK3CA mutations, RET rearrangements, and ROS1 rearrangements.¹⁸⁴ Targetable oncogenes in squamous cell carcinomas include tyrosine kinase inhibitors toward DDR2 mutations, FGFR1 amplification, and PIK3CA mutations.¹⁸⁴ Telomerase inhibitors may also have a role in treating NSCLC, including treating cancer stem cells.¹⁸⁵

In contrast to gene mutations, DNA methylation and histone deacetylation are reversible processes. Consequently, DNA demethylating drugs and histone deacetylase inhibitors have a theoretical benefit of altering the epigenetic changes involved in oncogenesis and, as a result, target multiple pathways simultaneously.³⁶ Unfortunately, these epigenetic agents have no proven benefit in solid tumors and could have a paradoxical result of promoting tumor growth through nonspecific effects on gene expression.³⁶

SUMMARY

Over the last 50 years, there have been significant advances in systemic chemotherapy, radiation therapy, perioperative patient care, and surgical techniques, including the emergence and development of minimally invasive techniques. During this same time period, there has also been a revolution in our understanding of biology, including the characterization of the structure of DNA, the discovery of oncogenes, and the development of targeted therapy against those oncogenes. As our understanding of the complex interwoven pathways of oncogenesis continues to evolve, our ability to make a significant impact on tumor biology through personalized oncology will lead to improvements in our patients' outcomes. The challenges that lie ahead are both stimulating and remarkable because the closer we think we are to understanding thoracic malignancies, the more we realize that "Biology is King."

IMPLICATIONS FOR THORACIC SURGICAL ONCOLOGISTS

SUMMARY

Lung cancer remains the number one cause of cancer-related deaths in men and women, and the incidence continues to rise with approximately 175,000 new cases diagnosed annually in the United States.¹ In this chapter, we review several innovative therapies for patients who are at high risk for primary and metastatic lung tumors. Application of these new therapies continues to evolve, and in most cases, surgical resection remains the mainstay of therapy. Lobectomy has been considered the standard treatment modality for early-stage non-small cell lung cancer (NSCLC) for years, with sublobar resection being suboptimal because of an increased potential for recurrent disease.² More recent data on small tumors (less than 2 cm) with good margins (with margin distance at least the diameter of the tumor) show the local recurrence rate has lowered to near that of lobectomy.³ However, most patients with NSCLC present with advanced disease, and a significant number of patients with early-stage disease are unable to undergo pulmonary resection because of compromised cardiopulmonary function or other reasons.⁴ The new alternatives to traditional surgical treatment allow additional options when surgery is not clearly of benefit or when the patient is not a candidate for traditional resection. As with other recent advances, such as video-assisted thoracoscopic surgery (VATS), these newer, less invasive approaches may allow surgeons to treat patients with thoracic malignancies even in the setting of marginal pulmonary reserve.⁵

The two principal ablative modalities discussed in this chapter for inoperable or high-risk patients are radiofrequency ablation and stereotactic radiosurgery. Another

ablative modality, microwave ablation, is also being evaluated, although current clinical experience with this novel approach is limited. We also briefly discuss some newer technologies for ablation, including irreversible electroporation. The main goal of these less invasive therapies is to locally destroy the pulmonary or thoracic neoplasm while preserving the surrounding normal tissues. In addition, we discuss intrathoracic chemoperfusion for pleural malignancies.

It is important that thoracic surgical oncologists stay abreast of new therapies, design clinical trials, and critically evaluate and report the results. The introduction of new technology should not change the paradigm of who treats thoracic malignancies. Failure of surgeons to adapt to new technology will lead to fragmentation in the care of the patient with a thoracic malignancy. However, for the time being, the current evaluable data support the concept that most localized thoracic malignancies should ideally still be treated by minimally invasive surgical resection. Thus, failure to involve an experienced thoracic surgical oncologist in the design of clinical trials will increase the risk of compromising patient care.

RADIOFREQUENCY ABLATION

Radiofrequency ablation (RFA) is a thermal ablative modality, which uses high-frequency alternating current to generate heat and coagulate tissue. RFA systems typically have three components: (1) a generator, (2) an active electrode that is placed within the tumor, and (3) a

FIGURE 46-1 ■ The radiofrequency ablation system.

dispersive electrode (Bovie pad) placed on the thighs of the patient (Fig. 46-1). As the radiofrequency energy moves from the active electrode to the dispersive electrode and back, ions within the tissue oscillate with the changing direction of the current, resulting in frictional heating of the tissue. As the temperature within the tissue rises to greater than 60° C, cell death occurs as a result of protein denaturation and coagulation necrosis. Moreover, the dispersion of energy beyond the vicinity of the active electrode is minimal, allowing for focused delivery of energy to the target lesion with minimal injury to the surrounding normal tissue. The advantages of this minimally invasive ablative approach include lower morbidity and mortality in comparison with the more invasive approaches, lower costs per treatment, lower costs to set up a program and the associated technology, reduced hospital stay, and the ability to complete treatment without multiple sessions.^{6,7} The goal of RFA in the treatment of lung tumors is complete coagulation necrosis of the lesion with a small margin of extension into adjacent normal pulmonary parenchyma.

Initial experience with RFA has been primarily in the treatment of liver tumors, both as an adjunct to resection and as primary therapy. Due to low complication rates, RFA may supplant other thermal ablative modalities (e.g., cryotherapy).^{8,9} Pulmonary RFA also has a low rate of major complications, which include sepsis, respiratory infection, bleeding, infection at the operative puncture site, and prolonged air leak.⁶ In a large international, multicenter study of 2320 patients who underwent percutaneous RFA for liver malignancies, the mortality

rate was 0.3%, and the overall complication rate was 7.1%.¹⁰

Several centers around the world have published reports demonstrating the safety and feasibility of RFA for lung tumors.^{11,12} Animal models, to investigate the feasibility of RFA for the treatment of lung tumors, have been used to develop treatment algorithms for humans. In a study by Goldberg and colleagues¹³ using a rabbit model of lung sarcoma, seven lesions were treated with RFA for 6 minutes at 90° C, and the remaining four tumors were left untreated as controls. The authors noted computed tomography (CT) evidence of coagulation necrosis surrounding the tumor, manifested radiographically by increased opacity enveloping the lesion. This was followed temporally by the development of central tissue attenuation consistent with cavitation. Histologic analysis revealed that at least 95% of the tumor nodules were necrotic, although some rabbits (43%) had residual tumor nests at the periphery of the tumor. Pneumothorax was the only procedure-related complication, occurring in 29% of treated rabbits and 25% of controls. In another study, Miao and colleagues¹⁴ implanted VX2 sarcomas into the lungs of 18 rabbits (12 treated and 6 controls). The lesions were then treated with RFA using a cooled-tip electrode. Absolute tumor eradication was achieved in 33% of the rabbits. A partial response was observed in 41.6% of rabbits that survived longer than 3 months. On histopathologic evaluation, the ablated lesions retained their fundamental tissue architecture with evidence of coagulation necrosis. Surrounding edema and inflammation were noted in the normal adjacent pulmonary parenchyma. One to 3 months after treatment, the ablated tumor became an atrophied nodule of coagulation necrosis within a fibrotic capsule.

The timing and progression of these postablation changes becomes an important issue when evaluating postprocedure treatment response in patients with pulmonary tumors. Some investigators have performed RFA followed by resection to evaluate the efficacy of the ablation procedure. In one multicenter study of 15 patients, ablation was possible in 13 cases.¹⁵ In these 13 patients, median tumor kill was 70%, with seven patients achieving 100% ablation. Five of the final six cases exhibited 100% ablation. Nguyen and colleagues¹⁶ published the results of an ablate-and-resect study in which vital immunohistochemical stains were used to assess tumor cell viability. In seven tumors studied with this technique, more than 80% nonviability was documented. Three patients (38%) demonstrated 100% nonviability. All three tumors were less than 2 cm in diameter. A single ablation with a 3- or 3.5-cm active electrode was performed, such that the larger tumors may have been inadequately ablated. Schneider and colleagues¹⁷ reported their series of ablate-and-resect pulmonary metastasectomies. Eighteen patients underwent RFA and subsequent thoracotomy and resection for 18 diverse solid tumor metastases. Lesion size ranged 0.7 to 2.5 cm. The resected specimens were evaluated for tumor viability with immunohistochemistry. Complete ablation was achieved in 39%. More than 90% ablation was achieved in 50% of the resected lesions, and the authors considered this to be a successful ablation, asserting that subsequent growth

FIGURE 46-2 ■ The LeVein (Boston Scientific, Boston, MA) needle electrode.

FIGURE 46-3 ■ The RITA (AngioDynamics, Latham, NY) electrode.

of the residual lesion (had it not been resected) was unlikely. An incomplete ablation (with less than 90% ablation) was documented in the remaining 11%. In another study, by Ambroggi and colleagues, a total of nine patients underwent RFA either by the CT-guided approach or by thoracotomy followed by resection.¹⁸ Complete ablation was noted in six of the nine patients (67%). These studies demonstrate that although RFA can produce effective ablation, 100% tumor cell death is not universally achieved and resection remains the treatment of choice for those able to tolerate surgical intervention.

Several U.S. Food and Drug Administration–approved devices are available for the performance of RFA, including (1) LeVein (Boston Scientific, Boston, MA), (2) RITA (AngioDynamics, Latham, NY), and (3) Valleylab (Covidien, Boulder, CO). The Boston Scientific and Covidien devices are impedance-based systems in which the end-point of treatment is determined by a significant rise in tissue impedance, indicating an inability of the target lesion to maintain further conduction and, therefore, ablation. The RITA system is a temperature-based device, which elevates the tumor temperature to predetermined lethal levels for a designated period of time. The Boston Scientific and AngioDynamics (Figs. 46-2 and 46-3) active probes consist of an expandable needle system, whereas the Covidien system consists of either a single needle or three parallel needles (Fig. 46-4) that are placed

FIGURE 46-4 ■ The Valleylab probe (Covidien, Boulder, CO).

within the tumor. The Covidien electrode consists of a proximal insulated portion and a distal uninsulated active tip. The electrode is irrigated with a continuous infusion of cold saline and for this reason is sometimes referred to as a “cool-tip” electrode. The dissolved saline ions enhance conduction and therefore theoretically decrease the required time to achieve effective ablation.

Two animal studies compared the relative efficacy of the various probes by assessing the region of ablation in a liver model.^{19,20} A recent Japanese report of RFA for treatment of 342 pulmonary tumors in 128 patients cites tumor size greater than 2 cm and use of the single-needle VL probe to be associated with local progression on multivariate analysis. Further analyses comparing the array probe and the internally cooled electrode for tumors showed that the use of the internally cooled electrode was an independent risk factor for local progression (hazard ratio [HR] 3.39; 95% confidence interval [CI], 1.56-7.38).²¹

Patient Selection

For stage I NSCLC, RFA should be reserved for those patients who are believed to be at increased risk for pulmonary resection and for those who refuse surgery. Occasionally, RFA may be a reasonable therapy for a medically inoperable patient with more advanced cancer (e.g., satellite nodules) localized to the lung.²² The efficacy of RFA is low for nodules greater than 5 cm in diameter. RFA is also not recommended for central lesions or those abutting the mediastinum.²³ Other patients who may be considered for treatment with RFA include those with advanced-stage disease who have responded to definitive radiation and chemotherapy but have a persistent solitary peripheral focus of cancer, and for those who present with a recurrent isolated cancer after previous lung resection. Leung and colleagues demonstrated that thermally ablative techniques, including RFA, applied to a previously irradiated field have the potential to enhance survival in patients with recurrent NSCLC.²⁴

RFA is also a suitable option for some patients with limited peripheral pulmonary metastases. Similar to resection, this treatment should be reserved for those patients with a limited number of metastases, disease localized to the chest, controlled or controllable primary

TABLE 46-1 Selection Criteria for Radiofrequency Ablation

Inclusion Criteria	Exclusion Criteria
NSCLC stage I or II*; poor surgical candidate	Tumor abutting hilum or large pulmonary vessel
NSCLC stage II (satellite nodule same lobe) or stage III/IV (nodule in another lobe or lung); poor surgical candidate	Malignant effusion
Stage IIIa or IV with solitary pulmonary nodule remaining after standard therapies	Pulmonary hypertension
Limited pulmonary metastases and recurrent disease; primary disease controlled or controllable; poor surgical candidate	More than three tumors in one lung
Target lesion ≤ 5 cm	Target lesion > 5 cm

*Patients with stage II should receive additional therapy because N1 disease will not be treated with radiofrequency ablation.
NSCLC, Non-small cell lung cancer.

sites, and for those patients who are believed to be at increased operative risk for resection of their pulmonary metastases. In some situations, complete resection of all pulmonary metastases is not possible, and RFA can be used as an adjunct intraoperatively. We have found RFA to be of use when a wedge resection of a peripheral nodule was performed and resection of other deeper nodules would have required a lobectomy or pneumonectomy. To preserve pulmonary parenchyma, some of these tumors were treated with intraoperative RFA via open thoracotomy. We recently reported the outcomes of RFA therapy for high-risk patients with pulmonary metastasis. Although surgical resection still remains the standard of care, we find RFA to be safe and feasible in selected patients or as a parenchymal-sparing approach in combination with surgical resection.²⁵ Table 46-1 outlines suggested selection criteria for the use of RFA.

Operative Technique

In our initial experience, RFA was performed via an open thoracotomy in some patients. This approach provides the most controlled method for RFA application but negates the most attractive attribute of the technology, that is, its nonoperative applicability. Surgical resection remains the standard of care for early-stage NSCLC. RFA should be used as an adjunct to surgery or as a sub-optimal substitute in patients unable or unwilling to undergo resection. Situations may arise, such as that described previously, in which a patient presents with two or more tumors, some amenable to resection and others to RFA. Although VATS has been postulated to be an attractive approach for the application of RFA, optimal needle deployment within the tumor in the setting of a collapsed lung is often difficult.

The most common method of pulmonary RFA entails percutaneous CT-guided administration. Either general or local anesthesia can be used when performing

CT-guided RFA. Our preference is to use general anesthesia.²⁶ This allows needle deployment, ablation, and biopsies (if required) to be performed in a more controlled manner. Additionally, some patients with cardiopulmonary compromise may have difficulty maintaining optimal body position if awake or sedated. Patient positioning is extremely important during CT-guided RFA. It is advantageous to position the patient in such a way that the target lesion is accessed with minimal penetration of normal lung parenchyma. This decreases the risks of hemorrhage and prolonged air leak. Positioning is also important to ensure adequate clearance of the RFA probe within the scanner. The maximum number of lesions that can be ablated in a single setting is debatable. As a general rule, however, ablation of more than three lesions in one setting is not recommended.

Treatment Response

RFA incites an inflammatory response that can persist for up to 3 months, making it difficult to determine radiographically whether the mass represents scar or viable cancer. The mass may initially appear larger on radiographic imaging and subsequently decrease in size. Ablated lesions may demonstrate central cavitation (Fig. 46-5) or develop bubble lucencies, both of which are radiographic indicators of effective ablation. Other centers have used CT densitometry protocols to evaluate for persistent or recurrent disease.²⁷ Densitometry involves the injection of contrast and subsequent CT images of the ablated nodule at 45, 180, and 300 seconds after the injection of contrast material. These densitometry techniques are time consuming and typically valuable only for those patients with single tumor nodules. The Response Evaluation Criteria in Solid Tumors has been modified to evaluate treatment responses objectively (Table 46-2).²⁵ CT scans are obtained at 3-month intervals to assess lesion size and characteristics. Whenever possible, positron emission tomography (PET) scans are also obtained to aid in the determination of tumor response. The American College of Surgeons Oncology Group (ACOSOG) completed a multicenter study evaluating RFA in high-risk patients with stage IA NSCLC. This study (Z4033) addresses such issues as response assessment by standardizing the follow-up protocol. The preliminary results have been presented, and final results are awaited.²⁸

Clinical Results

In our initial experience with RFA at the University of Pittsburgh, we treated 33 tumors in 18 patients.²³ Tumor pathologies included metastatic carcinoma ($n = 8$), sarcoma ($n = 5$), and NSCLC ($n = 5$). The mean age was 60 (range, 27 to 95) years. Our principal finding was the lack of effectiveness in treating tumors greater than 5 cm in size. Using the Response Evaluation Criteria in Solid Tumors, we found a radiographically determined response rate of 66% for tumors less than or equal to 5 cm in size, compared with only 33% in patients with tumors greater than 5 cm. A multicenter study summarizing the results of 493 percutaneous RFA procedures for pulmonary

nodules concluded that RFA was safe, with negligible morbidity and mortality (0.4%), and is associated with a gain in quality of life.²⁹

We reported our experience with RFA for the treatment of stage I NSCLC.³⁰ Nineteen patients underwent RFA over a 3-year period. Median age was 78 years

(range, 68 to 88). An initial complete response was observed in two patients (10.5%), partial response in 10 (53%), and stable disease in 5 (26%). Early progression occurred in two patients (10.5%). During follow-up, local progression occurred in eight nodules (42%), and the median time to progression was 27 months. There was no procedure-related mortality, although six deaths occurred during follow-up. The median follow-up in the remaining patients was 28 (range, 9-52) months. The probability of survival at 1 year was estimated to be 95% (95% CI, 0.85-1.0), and the median survival was not reached.

We have published a study of 100 patients who underwent image-guided RFA for lung malignancy.³¹ The median age was 73.5 years (range, 26 to 95 years), and there were 46 patients with primary lung cancer, 25 patients with recurrent lung cancer, and 29 patients with metastatic disease. The median hospital stay was 2 days (range, 1 to 33 days), and the most common complication was pneumothorax. Local progression occurred in the treated lesions in 35 patients, and median time to local progression was 15 months. The mean follow-up time was 17 months, and the median overall survival for the entire group was 23 months.

Lanuti and colleagues³² published their mid-term results of a series of 31 nonsurgical patients with NSCLC who underwent a total of 38 percutaneous RFA treatments. There were no 30-day mortalities. Five treatments resulted in pneumothoraces, and three required chest tubes. Six patients developed pneumonia within 4 weeks of treatment; all were resolved with oral antibiotics. There were eight cases of postprocedure pleural effusion. These are typical morbidities. The authors report that one patient developed transient laryngeal nerve injury following ablation of a right upper lobe lesion abutting the mediastinum. We reiterate that RFA should not be applied to central lesions. Tumor size ranged from 0.8 to 4.4 cm. Local recurrence was assessed via CT and PET and found in 31.5% of all treated tumors but in 50% of tumors greater than 3.0 cm, 44.4% in tumors 2.0 to 3.0 cm, and 21.7% in tumors less than 2.0 cm. Survival at median follow-up of 17.3 months was 74%, and overall survival was 30 months. Lanuti and associates recently published the results of a study assessing the management of locoregional recurrence in NSCLC.³³ From 2003 to 2010, 55 ablations were performed in 45 patients with a total of 21 locoregional recurrences following treatment.

FIGURE 46-5 ■ Radiographic evidence of tumor ablation: **A**, Before ablation. **B**, Three months after ablation; note central cavitation and overall decrease in size.

TABLE 46-2 Modified RECIST

Response	CT Mass Size	CT Mass Quality	PET
Complete (Two of the following)	Lesion disappearance (scar) less than 25% of original size	Cyst/cavity formation Low density of entire lesion	SUV < 2.5
Partial (One of the following)	More than 30% decrease in the LD of target lesion	Central necrosis or central cavitation with liquid density	Decreased SUV or area of FDG uptake
Stable lesion (One of the following)	Less than 30% decrease in the LD of target lesion	Mass solid appearance, no central necrosis or cavitation	Unchanged SUV or area of FDG uptake
Progression (Two of the following)	Increase of more than 20% in the LD of target lesion	Solid mass, invasion of adjacent structures	Higher SUV or larger area of FDG uptake

CT, Computed tomography; FDG, fluorodeoxyglucose; LD, largest diameter of lesion; PET, positron emission tomography; RECIST, Response Evaluation Criteria in Solid Tumors; SUV, standard uptake value of ¹⁸F-FDG on PET scan.

Mean tumor diameter was 2.3 cm (range, 0.7 to 4.5). Eighty percent of tumors that exceeded 3 cm in diameter were associated with locoregional recurrences. Overall survival was similar for patients who had locoregional recurrences compared with those who did not.

The RAPTURE study³⁴ was a prospective, intention-to-treat, single-arm, multicenter, international clinical trial designed to validate the feasibility and safety of RFA for pulmonary tumors as well as to assess efficacy. A total of 105 patients with 183 tumors were treated with 137 RFA treatments. All patients were deemed to be nonsurgical candidates. There were no mortalities. Twenty-seven patients developed a pneumothorax requiring chest tube evacuation. Pleural effusions occurred in 15 patients, 4 requiring drainage. Tumor sizes ranged 0.5 to 3.4 cm. Pulmonary function was assessed before the procedure and 1, 3, 6, and 12 months after the procedure and no significant change was found. Of the 85 patients who could be assessed for tumor response, 88% exhibited complete response to treatment at 1 year. Local progression was noted in 12%. Overall survival was 70%, and cancer-specific survival was 92% at 1 year.

Huang and associates³⁵ performed a study assessing the safety and efficacy of RFA for the treatment of pulmonary malignancy. Over a 7-year period, 329 patients (237 NSCLC and 92 metastasis) were treated with CT-guided RFA. The 30-day mortality rate was 0.6%, including 2 patients (one death from pericardial tamponade and another from hemoptysis), and there were postoperative complications in 113 of 329 (34.3%) patients. Complications included 63 (19.1%) pneumothorax, 15 (4.5%) pneumonia, 14 (4.2%) hemoptysis, 10 (3%) hemothorax, and 3 (0.9%) pericardial tamponade. Lesions greater than 4 cm were associated with a significantly increased risk of local progression. The median progression-free interval was 21.6 months, and 1-, 2-, and 5-year survival rates were 68.2%, 35.3%, and 20.1%, respectively. In conclusion, the authors deemed RFA to be a safe and effective procedure for the treatment of pulmonary malignancy but noted that it requires proper training and patient selection to limit complications.

ACOSOG completed a multicenter study (Z4033) that included 54 patients from 16 centers evaluating RFA in high-risk patients with stage IA NSCLC.²⁸ The preliminary results of this trial have been presented. The overall survival at 1 and 2 years was 87% and 70%, respectively. One-year local recurrence-free rate was 70%, and the 2-year rate was 61%. Change in the FEV₁ and diffusion of carbon monoxide in the lung (DLCO) at 24 months was not clinically significant. The final results of this trial are awaited.

These results demonstrate feasibility, safety, and intermediate-term results of RFA for pulmonary tumors not amenable to surgical resection. Techniques to more precisely localize the lesion under image guidance for ablative therapy are evolving; one such technique is electromagnetic navigation to aid RFA.³⁶ These technologies may improve the local progression rates after RFA. Further critical evaluation of ongoing clinical trials will aid in defining the impact of RFA on long-term tumor control and its potential applicability for larger tumors and more advanced disease.

STEREOTACTIC RADIOSURGERY

Conventional external beam radiation therapy is commonly used to primarily treat NSCLC when surgical resection is not possible. Unfortunately, cure is rare, local progression is common, and morbidity can be significant. Qiao and associates³⁷ summarized results from 18 studies reporting external beam radiation for stage I NSCLC. The mean 3- and 5-year survival rates were 34% and 21%, respectively. In one study of 71 node-negative patients who received at least 60 Gy of external beam radiation to their primary tumors, 3- and 5-year survival rates were only 19% and 12%.³⁸ In another study of radiation therapy in 60 patients with stage I or II NSCLC, local progression was documented in 53% of patients with a median progression-free survival of 18 months and an overall median survival of only 20.5 months.^{38a}

Higher radiation doses seem to enhance local tumor control.³⁹ Bradley and colleagues⁴⁰ showed that patients receiving greater than 70 Gy of radiation had better local control and cause-specific survival than those treated with lower doses. Increased doses of radiation, however, result in increased toxicity and damage to the surrounding pulmonary parenchyma. Radiation fibrosis seems to depend on the volume of lung radiated above a threshold of 20 to 30 Gy.⁴¹ Pulmonary toxicity is the major morbidity associated with external beam radiation treatment of NSCLC. Radiation pneumonitis is a potentially life-threatening sequela and occurred in 8.3% of patients treated with definitive radiotherapy.^{38a} Heightened toxicity, poor survival outcomes, and frequent local progression have prompted a growing interest in alternative means of irradiating pulmonary malignancy.

Techniques

Stereotactic radiosurgery (SRS; also referred to as stereotactic body radiotherapy [SBRT] or stereotactic ablative body radiotherapy [SABR]) is a relatively new approach that enables the selective delivery of an intense dose of high-energy radiation to a precise target volume. The improved accuracy is achieved through computer-controlled spatial localization of the tumor and delivery of multiple cross-fired beams of radiation that converge on the tumor, minimizing injury to surrounding normal tissue. In many centers, this technology has become standard treatment for intracranial tumors (gamma knife). Unlike in the brain, however, respiratory motion imposes technical difficulties for the precise delivery of radiation to lung tumors. Respiratory displacement is greatest near the diaphragm and less significant near the lung apices and adjacent to the carina. Several techniques are available to minimize the effects of respiratory motion on the precise delivery of the concentrated radiation. One approach is to use breath-holding techniques, often in combination with an abdominal compression device, to limit the ability of the diaphragm to move caudally.⁴²

At the University of Pittsburgh, we published the results of SRS using the CyberKnife stereotactic radiosurgery system (Accuray, Sunnyvale, California), a frameless SRS.⁴³ The Cyberknife system consists of a linear

accelerator radiation source that is mounted on a robotic arm (Fig. 46-6). Before initiating treatment, two to four small gold fiducials are implanted in the pulmonary parenchyma around the periphery of the tumor. This is accomplished either percutaneously via CT guidance or transbronchially under fluoroscopic guidance. At the time of therapy, cameras on the Cyberknife system use these markers to localize the tumor in space. The CyberKnife synchrony option records respiratory motion and combines this information with the fiducial images to optimize precise radiation delivery for any point of the respiratory cycle. A major advantage with this system

over those involving breath-holding and immobilization techniques is that the treatment times are shorter and therefore better tolerated by patients, who often have some degree of cardiopulmonary compromise (Fig. 46-7).

Patient Selection

Patient selection for SRS is similar to that for RFA, with some notable differences. One advantage of SRS is that central tumors can be safely treated, although dose-dependent toxicity still remains a concern. Therefore, we used a modified dose schema with a decreased dose (typically 12 Gy in 4 fractions) to treat central tumors. Additionally, we have found that osteosarcomas can be extremely difficult to penetrate with the RFA needle. Because SRS requires fiducials to be positioned close to a tumor rather than within it, SRS may be a better option for the treatment of metastatic osteosarcomas.

Results

Whyte and coworkers⁴⁴ published the first results of SRS for the treatment of lung tumors using the Cyberknife system. This study included 23 patients from two institutions. Respiratory gating was used in 14 patients and breath-holding in 9 patients. A single fraction of 15 Gy was used. Three patients developed pneumothoraces following fiducial placement. There was no radiation esophagitis or clinically apparent radiation pneumonitis. At a mean follow-up of 7 months, 2 patients (8.6%) had a complete response, 15 (65.2%) had a partial response, 4

FIGURE 46-6 ■ CyberKnife (Accuray) stereotactic robotic radio-surgery system.

FIGURE 46-7 ■ Computed tomographic scans of right lung squamous carcinoma treated with CyberKnife stereotactic radiosurgery (SRS). **A**, Before SRS treatment. **B**, Three months after treatment. **C**, Radiation plan with isodose mapping. **D**, Radiation paths.

(17.4%) had stable disease, and 2 (8.7%) had evidence of progression.

In our initial experience at the University of Pittsburgh, 32 patients (27 with NSCLC and 5 with pulmonary metastases) were treated with SRS using the Cyberknife system.⁴³ Patients were treated with 20 Gy in a single fraction. It should be noted that the radiobiology of SRS (by virtue of a high single focused dose) is different from that of external beam radiation. The biologically effective dose is much higher for SRS.⁴⁵ Biologic effective dose (BED) is based on the linear-quadratic equation and allows dose comparison among different institutions. $BED = nd(1 + d/[\alpha/\beta])$; where n = number of fractions, d = dose per fraction, and the α/β ratio value is unique to each tissue type ($\alpha/\beta = 3$ for normal lung parenchyma, $\alpha/\beta = 10$ for tumors).⁴⁶ It has been shown that higher biologically effective doses improve local progression-free survival.^{47,48} In our initial protocol, the 20-Gy dose was equivalent to a BED of 60 to 70 Gy with standard techniques.⁴³ Following SRS in the 32 patients, an initial complete response was seen in 7 (22%), partial response in 10 (31%), stable disease in 9 (28%), and progression in 5 (16%). The probability of 1-year overall survival for the entire group and stage I patients was 78% (95% CI, 0.65-0.94) and 91% (95% CI, 0.75-1), respectively.

We reported the results of 100 patients who underwent treatment with SRS for various pulmonary malignancies, including 46 patients with primary lung neoplasm, 35 with recurrent cancer, and 19 with pulmonary metastasis.⁴⁹ Patients were initially treated with a median dose of 20 Gy in a single fraction, which was later increased to 60 Gy in three fractions for peripheral lesions. Complications included pneumothorax in 26 patients (26%) following percutaneous fiducial placement, chronic obstructive pulmonary disease exacerbation in 1 patient, and 1 death a month after the initial SRS treatment. The initial response to treatment was measured using the modified RECIST criteria in 90 evaluable patients. Complete response was achieved in 20%, partial response was found in 29%, stable disease was observed in 22%, and progressive disease was noted in 29% of patients. Local progression, at the treated nodule, occurred in 25 patients with a median time to local progression of 22 months. The median follow-up time was 20 months, and the median overall survival of the entire group was 24 months, with an estimated 2-year overall survival of 50%. Increased SRS dose (60 Gy) was associated with lengthened time to local progression. With an increase in local progression, with a single fraction of 20 Gy for peripheral tumors, we have increased the dose to 60 Gy in three fractions for peripheral tumors.

The impact of SRS dose escalation on oncologic patient outcomes has been investigated. Timmerman and colleagues⁴² previously reported the results of a dose escalation study in 37 patients with stage I NSCLC. A breath-holding technique with abdominal compression was used. In this series, the dose was escalated from 20 to 60 Gy in three fractions. Complete response was seen in 27% of patients and a partial response in 60%. At a median follow-up of 15 months, six patients (16.2%) had experienced local failure and all six received fractions lower than 18 Gy, supporting the concept of dose escalation.

The same group published a follow-up study 2 years later.⁵⁰ Stage I NSCLC patients were stratified into T1 and T2 tumors. Dose-limiting toxicity included bronchitis, pericardial effusion, hypoxia, and pneumonitis. Local failure occurred in four (21%) of the T1 tumors and six (21%) of the T2 tumors. In the T1 tumors, eight (42%) patients had regional or distant recurrences (or both). In the T2 tumors, six (21%) had regional or distant recurrence.

Although an increased dose delivered during SRS may improve local control, an increased dose is also associated with increased toxicity, when treating central lesions.⁵¹⁻⁵³ In a phase II study of 70 medically inoperable stage I NSCLC patients treated with SRS using 60 to 66 Gy in three fractions, local control was found in 95% of the patients, and the estimated 2-year overall survival rate was 54.7%.⁵² However, increased toxicity was noted in central tumors, with a 2-year freedom from severe toxicity of 54% in central lesions compared with 83% in peripheral lesions. During a median follow-up of 17.5 months, 6 of the 70 patients (8.6%) died of treatment-related causes. These results led the authors to conclude that this regimen should not be used for patients with tumors near central airways. In view of these data, we use a dose of 60 Gy in three fractions for peripheral lesions, and we currently use a modified dose schema with 48 Gy in four fractions for central tumors.

Dose escalation for locally advanced cancer with a SBRT "boost" in addition to conventional chemoradiotherapy is also a current treatment modality being investigated. Karam and colleagues⁵⁴ reported the results of a study including 16 patients with locally advanced NSCLC who were treated with an average dose of 25 Gy (range, 20 to 30 Gy) with SBRT. The SBRT was in addition to a median dose of 50.4 Gy of conventional chemoradiotherapy. One-year overall survival for the patient group was 78% with a median time to cancer progression of 10 months. The authors concluded that dose elevation using SBRT in addition to conventional external beam radiotherapy is a feasible option for locally advanced NSCLC.

Several additional case series have also been published.⁵⁵⁻⁵⁸ A review by Nguyen and colleagues⁴⁶ compared effectiveness and morbidity of the published VATS lobectomy data (19 studies, 3988 patients) with the published SRS data (24 studies, 1485 patients) for early-stage NSCLC. The SRS data were further subgrouped into studies that reported a BED of at least 100 Gy (14 studies) and those that reported a BED of less than 100 Gy (10 studies). Local control and survival rates were comparable for studies that used a BED of 100 Gy or more. The mortality rate was 1% for the VATS group and 0.4% for the SRS group that received more than 100 Gy. All of the SRS deaths (6 patients) were noted to be from a single study that used a BED of >180 Gy to centrally located tumors. Morbidity was a mean of 16% for the VATS group (prolonged air leak, arrhythmia, pneumonia, stroke, pulmonary embolism) versus a mean of 4% for the entire SRS group (grade 3-4 pneumonitis, rib fractures, pleural effusion). VATS 2- to 5-year survival ranged from 60% to 96%. Actuarial survival for the SRS group that received more than 100 Gy ranged from 42% to 91%, and that for the SRS group that received less than 100 Gy

ranged from 24% to 90%. Local control, although not reported in all studies, ranged from 88% to 100% for the VATS group, 74% to 100% for the SRS group that received more than 100 Gy, and 57% to 91% for the SRS group that received less than 100 Gy. The authors note that SRS is feasible and associated with minimal morbidity, and delivery of more than 100 Gy appears comparable with VATS lobectomy with respect to local control.⁴⁶ We have modified our initial protocol of delivering a single 20-Gy fraction to now include a total of three fractions for peripheral lesions and four fractions for central lesions to achieve a BED of more than 100 Gy.

Onishi and associates⁵⁹ reported the Japanese multi-institutional SBRT data. Ninety-nine patients who were surgical candidates but refused surgery underwent SRS. The 5-year overall survival for operable patients was 70.8% for those patients treated with BED more than 100 Gy and 30.2% for those treated with BED less than 100 Gy. Multi-institutional phase II studies of SRS have been reported for the treatment of potentially resectable stage I NSCLC in Japan (JCOG 0403) and the United States (RTOG 0236). Another phase II multi-institutional study (NCT00643318) investigating Cyberknife SRS for medically inoperable stage I NSCLC, led by the University of Pittsburgh, is in progress. There are two randomized multi-institutional studies on surgical resection with SRS in operable patients with stage I NSCLC that were initiated; however, they were terminated due to low accrual. One study (STARS; NCT00840749) was led by MD Anderson Cancer Center group, and another study (ROSEL; NCT00687986) was based in the Netherlands. The Netherlands study did not require tissue confirmation of lung cancer, which will impact the interpretation of the results.

Timmerman and colleagues⁶⁰ recently reported the 3-year results of a prospective phase II multicenter study (RTOG 0236) including 59 (55 evaluable) patients who underwent SBRT for inoperable early-stage lung cancer. The median follow-up time for the 55 evaluable patients was 34.4 months (range, 4.8 to 49.9). A complete response to SBRT was achieved in 28 patients, a partial response was reported in 21 patients, and the combined sum of complete and partial responses accounted for 89% of patient responses to treatment. The 3-year primary tumor control rate was 97.6%, with only one patient having a recurrence or progression at the primary tumor site. The 3-year disease free survival and overall survival rates were 48.3% and 55.8%, respectively. For the entire group of patients, the median disease-free survival and overall survival rates were 34.4 and 48.1 months, respectively. The initial results of a large phase II multicenter trial of Cyberknife SRS for medically inoperable patients, led by investigators from the University of Pittsburgh, has been presented.⁶¹ In this large multicenter trial, 78 patients with stage I NSCLC were treated with SRS (60 Gy in three fractions). The median follow-up was 26 months. The probability of 2-year cancer-specific survival was 79%. During follow-up, 3.8% of patients had local progression only. The authors concluded that the intermediate-term results of SRS are promising. Additional follow-up is currently ongoing to fully evaluate the results of SRS in this trial.

Fakiris and coworkers reported the updated results of a prospective phase II study assessing the outcomes of 70 medically inoperable patients who underwent SBRT for stage T1 ($n = 34$) and T2 ($n = 36$) NSCLC.⁶² Treatment was delivered at 80% isodose volume and consisted of total doses of 60 Gy (three fractions of 20 Gy) for patients with T1 tumors and 66 Gy (three fractions of 22) for patients with T2 tumors.

Median follow-up was 50.2 months (range, 1.4 to 64.8), which consisted of the results for all 70 patients who completed SBRT as initially planned. The 3-year overall survival rate was 42.7% (95% CI, 31.1%-54.3%), and the median survival rate was 32.4 months. Patients with T1 tumors had a median survival rate of 38.7 months, and patients with T2 tumors had a median survival rate of 24.5 months.

Summary

Neither of the aforementioned novel treatment modalities is as effective as surgical resection. RFA ablates lesions from the inside-out, with treatment failures typically seen at the periphery of the lesion. SRS, on the other hand, can be configured to deliver a concentrated dose to the entire target volume, usually encompassing a small amount of normal lung parenchyma surrounding the lesion. At the University of Pittsburgh, we typically place fiducial markers during RFA for lesions greater than 3 cm or for asymmetrical lesions in which a uniform ablation is not likely to be achieved. During follow-up, if persistent tumor is suspected, it can be retreated with either another RFA application or SRS. We use SRS more often than RFA for such scenarios.

MICROWAVE ABLATION

Microwave ablation (MWA) is a relatively recent promising tumor ablation modality. Microwaves comprise the zone of electromagnetic radiation between 900 and 2450 MHz. The waves possess electrical properties, with the charge changing from positive to negative as the wave travels from peak to trough. As microwave radiation interacts with water, the individual polar molecules oscillate, flipping back and forth with the changing charge of the microwave. Because of the high frequency, the water molecules change direction 2 to 5 billion times per second. The resulting friction produces heat. This dielectric heating can be of sufficient magnitude to coagulate protein and cause cell death.^{63,64}

Like RFA, MWA is amenable to percutaneous and open approaches. In general, a microwave antenna is inserted into a target lesion via CT guidance in much the same way as is an RFA probe. The antenna is insulated throughout most of its length, with a variable length of exposed tip. The antenna is connected to a microwave generator, which emits an electromagnetic wave. This leads to excitation of water molecules, subsequent friction and heat generation, and, ultimately, coagulation necrosis. Unlike RFA, a dispersive electrode is not necessary. Moreover, multiple antennae can be activated simultaneously (multiple active antennae per lesion and/or

treatment of multiple lesions simultaneously). MWA may allow temperatures within the targeted lesions to be driven higher, resulting in a larger ablation zone in a shorter period of time.⁶⁴ As with RFA, the initial clinical experience with MWA has been in the treatment of liver tumors.⁶⁴⁻⁶⁶

Clinical experience with MWA for the treatment of lung tumors is relatively limited but there are few studies evaluating the use of MWA for lung malignancy. Feng and coworkers⁶⁷ reported the application of MWA to 28 lung tumors in 20 patients. A response of 50% or more was noted in 13 (46.4%) of the nodules and a complete response in 3 (10.7%). No significant complications were noted. An ablate-and-resect study was performed by Simon and colleagues.⁶⁴ Patients underwent MWA prior to planned resection. The mean tumor diameter was 3 cm (range, 2 to 5.5 cm), with an average tumor volume of 7.1 cm³. The maximum ablation achieved was 4 cm (3 to 5 cm), with an ablation zone volume of 23.4 cm³.

Belfiore and associates⁶⁸ reported the results of a study that included MWA treatment of 69 separate lung lesions in 56 patients (44 patients with lung cancer lesion, 12 patients with metastatic disease). Complications included pneumothorax in 18 patients with chest tubes being required in 8 patients, 10 patients had pain (mild to moderate) at the site of needle insertion, and fever occurred in 4 patients. The overall survival rates at 12, 24, and 36 months were 69%, 54%, and 49%, respectively. The estimated mean survival time was 27.8 months.

Lu and colleagues⁶⁹ performed a study of 69 patients who underwent percutaneous MWA therapy for pulmonary malignancy. The entire group consisted of varying stages of cancer, including 22 patients with recurrent cancer, 21 patients with metastases, and 26 patients with primary lung malignancies. For patients with NSCLC, the cancer stages included 7 (14.58%) stage I, 10 (20.83%) stage II, 22 (45.84%) stage III, and 9 (18.75%) stage IV. The most common complication was pneumothorax, which varied in severity and occurred in 13 (18.84%) patients. Local tumor progression rate based on a 3-year analysis was 16.13%, occurring in 15 patients. The 1-, 2-, and 3-year overall survival rates for patients with NSCLC were 75%, 54.2%, and 29.2%, respectively. Patients with metastatic lung tumors had 1-, 2-, and 3-year survival rates of 47.6%, 23.8%, and 14.3%, respectively.

Wolf and coworkers⁷⁰ published their retrospective experience using CT-guided MWA to treat 82 lung tumors (primary NSCLC and metastases) in 50 patients. Tumor size was a mean of 3.5 cm $\pm$ 1.6 cm. A single antenna was used for lesions 2 cm in size or less; multiple antennae were used to treat lesions greater than 2 cm. Follow-up evaluation consisted of CT and PET imaging. The 30-day mortality rate was 0.0%. Morbidities included acute respiratory distress syndrome (1 patient, 2% of ablations), cutaneous burns (2 patients, 3%), pneumothorax (26 patients, 39%; 8 patients required chest tube), minor hemoptysis (4 patients, 6%), pain (1 patient, 2%), postablation syndrome (1 patient, 2%), and infection (2 patients, 3%). At mean follow-up of 10 months, 48% had residual or recurrent disease. Local control at 1 year was 67%, and mean time to first recurrence was 16.2 months.

Actuarial survival was 65%, 55%, and 45% at 1, 2, and 3 years, respectively. Cancer-specific survival was 83%, 73%, and 61% at 1, 2, and 3 years respectively. Tumor size larger than 3 cm was not significantly associated with decreased local control or survival. Radiographic evidence of postablation lesion cavitation was associated with reduced cancer-specific mortality.

Wolf and associates⁷¹ recently published a prospective ablation and resection study including 10 patients who underwent intraoperative MWA for pulmonary malignancies. Tumor histology varied and included 3 patients with squamous cell carcinoma, 5 patients with adenocarcinoma, and 2 with metastatic tumors. The maximal tumor diameter was a mean of 2.4 cm, and the maximum diameter of the ablation zone (based on five tumor specimens) was 4.8 cm. Postoperative histologic characteristics of the ablation zones included coagulation necrosis, amorphous cytoplasm, no discernible cellular membrane, and a loss of cell structure. On further examination of the ablation zones using vital histochemical nicotinamide adenine dinucleotide staining, it was confirmed that six specimens had coagulation necrosis extending into the peritumoral parenchyma, and cellular death was noted beyond demarcated transition zones between viable and unviable ablated cells. Five of the six ablation zones were deemed a complete ablation. Other than minor air leak, no complications were identified strictly for the MWA, although there was one postoperative death from pneumonia and respiratory failure attributed to surgical resection. It was concluded that the peritumoral ablation zone could potentially be considered the equivalent of an oncologic resection margin. Although this study has encouraging results, we believe that a cautionary note should be taken with the understanding that only 50% of patients (5 of 10) had verification of complete cellular death in ablation zones. Further studies are needed to support MWA as a treatment modality capable of providing consistent microscopically negative tumor margins.

MWA potentially results in higher intratumoral temperatures, potentially larger ablation zones, and faster treatment times. Additional experience with this modality, along with refinements in equipment and techniques, is necessary before the role of MWA can be established in the treatment of early-stage lung cancer.

CRYOABLATION

Cryotherapy is another ablative modality for the treatment of pulmonary malignancy and is essentially a method for inducing tumor death by cellular freezing. Cryosurgery has been used for several other cancers.⁷²⁻⁷⁵ Similar to RFA, cryoablation is best suited for patients who are not candidates for resection.⁷² Cryotherapy can be performed through various routes, including endobronchially and percutaneously. There are few reports of cryotherapy for lung tumors.

Wang and coworkers⁷⁶ reported the results in 187 patients who underwent CT-guided percutaneous cryotherapy for thoracic cancer masses. CT imaging was used to compare low-attenuation ice formation with the size and location of the initial tumor that was treated. Mean

tumor coverage with low-attenuated ice formation was 99% for peripheral lesions 4 cm or less ($n = 101$) and 80% for centrally located ($n = 58$) masses greater than 4 cm. Kawamura and associates⁷⁷ applied the use of cryotherapy for the treatment of small pulmonary metastases. Cryoablation was performed for 35 tumors in 20 patients. The 1-year survival rate was 89.4%, and 7 (35%) patients had local recurrence during a median follow-up of 21 months.

CHEMOPERFUSION OF THE PLEURAL CAVITY

The results of surgical therapy alone or combined with traditional chemotherapy or radiation therapy have been disappointing for patients with malignant pleural mesothelioma or patients with diffuse pleural disease from thymic malignancies. The standard of care for most of these malignancies continues to evolve. Baldini and colleagues⁷⁸ reviewed a series of patients who underwent multimodal therapy for malignant pleural mesothelioma. In this series, 54% of patients developed recurrences, of which the site of recurrence included the ipsilateral hemithorax in 35% of patients. Several strategies have been investigated to improve the local control of disease, after macroscopic complete resection (MCR). One method for the treatment of malignant pleural mesothelioma is to surgically remove all gross disease (complete macroscopic resection) and then bathe the hemithorax with cytotoxic agents (chemoperfusion) with or without hyperthermia. The advantage of this approach is the direct exposure of any residual microscopic disease to higher drug concentrations than that achievable via conventional (systemic) chemotherapy, while also minimizing the toxic systemic side effects. Adding hyperthermia to this strategy has been shown in some studies to increase the local tissue and cellular concentrations of the chemotherapeutic agent compared with normothermic perfusion.⁷⁹ The drug most commonly reported for use in intrapleural hyperthermic chemoperfusion is cisplatin. Early experience with “chemothermotherapy,” using intrathoracic bolus injection of cisplatin, suggested the potential efficacy of using postoperative hyperthermic chemotherapy for the treatment of carcinomatous pleuritis.⁸⁰

Most of the experience with hyperthermic intraoperative chemoperfusion (HIOC) has been in the treatment of intraperitoneal malignancies.⁷⁹⁻⁸¹ A few centers have published results of nonrandomized trials of cytoreductive surgery followed by intraoperative hyperthermic intrathoracic perfusion chemotherapy. In most centers, this application is limited to clinical trials, with most of the experience being reported for patients with malignant mesothelioma and, to a lesser degree, thymic malignancies. Relatively few data exist for the application of chemoperfusion for the treatment of stage IIIB NSCLC. Although a cautionary note must be added regarding efficacy, these reports have demonstrated feasibility and some optimism that local control and, in some cases, survival may be better in comparison with historical controls.

The optimal temperature of the perfusate is unknown, but temperatures higher than 43° C may be associated

with an increased risk of pulmonary edema if the ipsilateral lung remains in situ, for example, after pleurectomy alone. One of the main concerns of HIOC is renal toxicity. In the case of extrapleural pneumonectomy, perfusion at the same operative setting as the resection may lead to an increased risk of postpneumonectomy pulmonary edema as a result of the aggressive hydration that is routinely administered to minimize the renal toxicity of cisplatin. In our experience, if extrapleural pneumonectomy is performed, we may consider delay of hyperthermic chemoperfusion with cisplatin for a few days. If the contralateral lung is functioning well at that point, and there is minimal oxygen requirement, we return to the operating room and hydrate the patient aggressively for renal protection. We then perform the hyperthermic chemoperfusion using videothoroscopic access. Several adjuncts have been proposed to reduce the renal toxicity in these patients. These include admission of the patient a day before surgery and administration of intravenous hydration overnight, prior to resection and HIOC. In addition, there have been clinical investigations with pharmacologic cytoprotection with amifostine and sodium thiosulfate.^{84,85} In general, the technique involves MCR, followed by amifostine infusion. After hemostasis is achieved, HIOC is performed with cisplatin at a temperature of 42° C. At the conclusion of the intrapleural lavage, intravenous sodium thiosulfate is administered to bind and inactivate residual circulating cisplatin. Some of the clinical trials on chemoperfusion are summarized next.^{82,83}

Zellos and colleagues⁸⁴ performed a study of 42 patients in a prospectively enrolled protocol for treatment with intraoperative hyperthermic cisplatin for malignant pleural mesothelioma. In this study, amifostine was used in an attempt to decrease the renal toxicity of cisplatin. Amifostine was administered before hyperthermic chemoperfusion. Twenty-nine patients underwent extrapleural pneumonectomy followed by intraoperative hyperthermic cisplatin perfusion in the abdomen and chest for 1 hour at 42° C. Median postoperative hospital stay was 15 days, and the most common complications were atrial fibrillation in 19 patients (66%) and deep venous thrombosis in 9 patients (31%). Fifteen patients received elevated doses of cisplatin (175 to 200 mg/m²) and had improved survival at 26 months compared with the 14 patients who received lower doses (75 to 150 mg/m²) of cisplatin, who had a median survival of 16 months.

Tilleman and associates⁸⁵ reported the results of a phase II prospective study of 121 patients who were enrolled to undergo extrapleural pneumonectomy followed by intraoperative intracavitary hyperthermic cisplatin therapy (dose of 225 mg/m²) for malignant pleural mesothelioma. In this study, intravenous amifostine was administered before the cisplatin lavage, and intravenous sodium thiosulfate was administered immediately after chemoperfusion to enhance the renal protection. Of the 121 patients initially enrolled, 96 patients underwent extrapleural pneumonectomy. Of these 96 patients, 92 had cisplatin perfusion following extrapleural pneumonectomy. There was a reduction in renal toxicity for the amifostine and sodium thiosulfate group (1 of 27) when compared to the sodium thiosulfate group alone (7 of 65).

Disease recurrence occurred in 47 of 92 (51.1%) patients with a mean disease-free interval of 15.3 months. Median follow-up was 31.2 months (range, 16.7 to 45.8 months), and median overall survival (121 patients) was 12.8 months. Median survival was 11 months for those patients who did not undergo treatment based on the HIOC protocol compared with a median survival of 13.1 months for the treatment group (92 patients). Patients with early-stage disease (stage I or II) had a statistically significant ($P = 0.0071$) improved median survival (21.3 months) in comparison with patients with stage III disease (11.5 months). The overall cancer-specific survival for the treatment group was 16.9 months.

In one report, Yellin and colleagues⁸¹ described the results of hyperthermic pleural perfusion with cisplatin in a heterogeneous group of patients with malignant pleural involvement. This group of 26 patients included 7 with malignant mesothelioma, 7 with stage IVA thymoma, 4 with thymic carcinoma, 1 with chest wall sarcoma, 3 with NSCLC, 2 with metastatic sarcoma, and 2 with metastatic carcinoma (1 ovarian, 1 squamous of unknown origin). Surgical resection of all gross disease was attempted with resection and pleurectomy in 10, extrapleural pneumonectomy in 8, and incomplete resections in the other patients. Hyperthermic chemoperfusion was performed with cisplatin at various concentrations at an infusion temperature of 42° C for 1 hour. Intrapleural temperatures ranged from 40.1° C to 41.5° C with a maximal systemic temperature of 38° C. Creatinine clearance remained unchanged in all patients, and no significant hematologic toxicities were reported, except for a single patient with thrombocytopenia following chemotherapy. The most notable postoperative complication was empyema, which occurred in 4 of 26 patients (15%). There was one postoperative death from a gastric herniation. Complete ipsilateral pleuropulmonary control of disease was reported in 17 of 24 (71%) evaluable patients. Overall 3-year survival was 44% in this group of patients.

In a report by de Bree and associates from the Netherlands Cancer Institute,⁸⁶ cytoreductive surgery was performed for 11 patients with malignant mesothelioma and 3 patients with pleural thymoma metastases. This was followed by hyperthermic chemoperfusion of the pleural cavity with a combination of Adriamycin and cisplatin. In the thymoma group, four perfusions were performed for three patients (one patient with a second operation for contralateral pleural metastases discovered on follow-up). Complications included one grade 2 nephrotoxicity and one wound dehiscence. At an early follow-up of 18 months, all three patients were alive and free of disease. In a follow-up comment, however, two of the patients suffered disease recurrence.⁸⁷ In the mesothelioma group, at a mean follow-up of 7.4 months, there were three recurrences with two of the patients dying of contralateral pleural and peritoneal disease.

The same group⁸⁸ more recently reported a comparison of 20 patients with mesothelioma treated with cytoreductive surgery and hyperthermic chemoperfusion with another 15 mesothelioma patients treated with extrapleural pneumonectomy and postoperative hemithoracic radiation to 54 Gy (no chemoperfusion). The

chemoperfusion group suffered the only postoperative mortalities (two [10%]), more complications (70% vs. 53%), and shorter survival (11 months vs. 29 months; $P = \text{ns}$). Local control was 67% versus 20% for the extrapleural pneumonectomy/radiation therapy group and hyperthermic chemoperfusion group, respectively. Median time to local recurrence was not reached in the extrapleural pneumonectomy/radiation therapy group and was 9 months in the chemoperfusion group ($P = 0.003$). Although feasible, and with results not unlike historical controls, hyperthermic chemoperfusion was associated with significant morbidity and a relatively short term of local control.

Richards and colleagues⁸⁹ reported their experience of 44 patients with malignant pleural mesothelioma who underwent resection followed by intraoperative intracavitary chemoperfusion with escalating doses of cisplatin. They report an 11% mortality rate, dose-limiting renal toxicity with a cisplatin dose of 250 mg/m², atrial fibrillation (32%), acute respiratory distress syndrome (11%), pneumonia (9%), and deep venous thrombosis (9%). A significant difference in survival was seen between those patients receiving low-dose hyperthermic chemoperfusion (50 to 150 mg/m²; median survival, 6 months) and those receiving higher, but not toxic, doses (175 to 250 mg/m²; median survival, 18 months).

Recently Sugarbaker and colleagues⁸³ studied a cohort of 103 patients with malignant pleural mesothelioma undergoing surgical MCR. Of the 103 patients, 72 underwent hyperthermic intraoperative cisplatin chemotherapy. The 72 patients treated with HIOC had a significantly lengthened interval (27.1 months) until recurrence compared with the 31 patients who did not have hyperthermic cisplatin (12.8 months). Furthermore, the overall survival for the HIOC group (35.3 months) was improved compared with the group not treated with hyperthermic cisplatin (22.8 months).

Although some encouraging results of chemoperfusion have emerged from selected centers, the precise role of intracavitary chemotherapy with or without hyperthermia for thoracic malignancies with extensive pleural involvement is not clear. Further clinical trials are required to determine the ideal candidates, optimal chemotherapeutic agent(s), and the timing and temperature of the perfusate. Logical inclusion criteria would consist of patients with disease confined to one pleural cavity, ability for gross tumor removal of all local disease, and lack of distant extrathoracic metastasis.

MODALITIES CURRENTLY UNDER INVESTIGATION

Recent modalities under investigation for the treatment of lung tumors include bronchoscopy-guided RFA, high-intensity focused ultrasound, and irreversible electroporation. Results of both animal and human studies have demonstrated bronchoscopy-guided internally cooled RFA as a potentially "safe and feasible" procedure for the treatment of lung tumors.^{90,91} High-intensity focused ultrasound has been shown to target cancerous lesions with highly precise ablation. However, most clinical trials

evaluating the efficacy of high-intensity focused ultrasound are for malignancies other than lung cancer because of the inherent limitations (unfavorable environment for ultrasound application) of the ventilated lung. A recent study using *in vivo* porcine tumors and an *ex vivo* human lung model have proposed “lung flooding,” whereby the lung is filled with isotonic saline until functional residual capacity is reached, as a potential solution to the problems with the lung environment as a result of lung ventilation.⁹² Irreversible electroporation functions by the proposed mechanism of generating electrical pulses that affect the cellular membrane by the formation of pores (electroporation) causing irreversible cell death and tumor ablation.⁹³ Irreversible electroporation is different from other ablative techniques in that it causes tumor cell death with a nonthermal mechanism, which serves as the primary impetus for the application of this modality to tumor ablation. It is believed that irreversible electroporation is not susceptible to the “heat sink effect” caused by thermal ablation (RFA, MWA) and can therefore be used more efficiently adjacent to large vessels.⁹³⁻⁹⁶ Preliminary results of a recent porcine study indicate that irreversible electroporation has both a nonthermal and an “extracellular matrix sparing” mechanism of action for tumor ablation.⁹⁷

IMPLICATIONS FOR THORACIC SURGICAL ONCOLOGISTS

With the advent of percutaneous ablation techniques for the treatment of early-stage lung cancer, controversy has emerged regarding the optimal approach to treating these patients. Furthermore, with the National Lung Screening Trial (NLST) showing benefits of early detection of lung cancer in selected patients^{98,99} and with the increasing use of CT screening, many small lung lesions are being discovered, some of which are found in older adult and high-risk patients. Controversy with regard to percutaneous ablation techniques is driven by the emergence of novel technology that spans the practice venues of several disciplines, including interventional radiologists, pulmonologists, and thoracic surgical oncologists. Some are eager to proceed, but a careful comparison with surgery makes others wary to relinquish surgical management of patients with lung cancer. However, as patients’ natural tendency to seek out less invasive interventions continues, the detection of smaller, earlier, and more easily treatable lesions is becoming more commonplace, and we are seeing many patients choose the least invasive option. Thus, the question remains regarding which patients should be referred for these new, less invasive but potentially less effective treatments. Another remaining question is who should be performing these procedures—should it be experienced interventional radiologists with surgical backup, or thoracic surgeons with extensive experience in open and minimally invasive resection techniques who now have training in percutaneous CT-guided techniques, or a combined team approach whereby the radiologist performs the biopsy and the surgeon performs the ablation? A variety of scenarios have occurred at different centers,

based on institutional and departmental biases and the available expertise and interest of the surgical and radiology staff.

A similar procedural evolution occurred with the implementation of VATS techniques. The Society of Thoracic Surgeons/American Association for Thoracic Surgery position statement on VATS recommends that such procedures be performed by surgeons familiar with open thoracic surgical approaches and the management of their complications. The surgeon must have the judgment, training, and capability to proceed to an open thoracic procedure if necessary and should personally guide the preoperative and postoperative care of the patient.¹⁰⁰ Although some interventional radiologists may have the experience and ability to perform difficult percutaneous interventions, there is great variability in their clinical training, and many may have never studied or treated patients with lung cancer. Conversely, many thoracic surgeons have dedicated their entire training and career to treating lung cancer and perform minimally invasive and percutaneous procedures on a routine basis. Thoracic surgeons are specifically trained in the areas of pulmonary physiology, thoracic oncology, pulmonary surgery, and lymph node evaluation and are personally capable of managing procedure-related complications. In addition, they have been, and continue to be, involved in the primary workup and follow-up care of patients with lung cancer and have developed a historical association with consultants in the management of this disease.

There is no doubt, however, that complacency of thoracic surgical leadership can lead to a critical deficiency in embracing and incorporating these new techniques in a timely manner, resulting in a loss of thoracic surgeons trained in the appropriate application of these modalities. Credentialing is also an important and controversial issue. Hospital administration and departmental guidelines have to be established to identify those physicians approved to conduct these procedures. Surgeons need to complete a dedicated didactic session covering the basic knowledge base and techniques, in conjunction with a period of proctorship until proficiency is demonstrated after performing a prescribed number of supervised interventions. Currently, there are no nationally accepted standards for the credentialing of surgeons to perform RFA within the chest.

Gaining access to a CT scanner can also be a complicated process. Operating rooms with built-in CT scanners offer the ideal environment for performing these procedures but are not yet available in many centers. However, in the operating room setting, the necessary surgical equipment and staff are on hand, making the procedure and any complications safer and more efficient to manage. If the procedures must be performed in the radiology suite, thoracic surgeons should work in a collaborative fashion with the interventional radiology colleagues. The room must be capable of supporting an anesthesia circuit, with built-in oxygen and suction. All supplies related to the procedure must be stored on-site or in a portable cart. Quality assurance programs must be implemented to ensure optimal patient outcomes, with a database monitoring treatment morbidity and mortality profiles. Thoracic surgeons are best suited to

make the decision as to which surgical or ablative modality to use in any given clinical setting. Whether to use an open, thorascopic, percutaneous technique or SRS to manage a patient with a small pulmonary nodule requires careful judgment and expertise with each technique to ensure an optimal oncologic outcome. Certainly, percutaneous and other ablative therapeutic modalities will ultimately have a role in high-risk patients with compromised lung function.

Decision making can be even more complex in managing patients with difficult lesions, such as ground glass opacities. These lesions tend to be small and slow-growing and have a more indolent natural history. Some of these lesions may represent carcinoma in situ or minimally invasive cancers in which case anatomic resection with or without lymph node dissection may not always be necessary.¹⁰¹ The use of percutaneous ablative techniques in this setting may represent an ideal utilization of the technology.

As these innovative techniques are developed and refined, careful attention must be paid to several important pitfalls, including overapplication in the setting of indeterminate solitary pulmonary nodules, inappropriate or inadequate management of small to medium-sized lung tumors, inappropriate interventions directed toward metastatic disease, and the risk of inadequately staging patients prior to intervention. To avoid these pitfalls, thoracic surgeons should maintain a leadership position in the deployment of these techniques for the treatment of patients with thoracic malignancies.

SUMMARY

RFA and SRS have been demonstrated to be safe with reasonable efficacy in the treatment of small lung tumors. RFA appears to have a higher rate of local progression when compared with SRS; however, with evolving techniques of tumor localization for image-guided ablation of tumors, these results may improve with more precise image-guided percutaneous ablation.²⁹ RFA can be performed in one treatment session, whereas it now appears that SRS is more effective if larger doses of radiation over three to four fractions are performed. RFA is not recommended for centrally based tumors. In addition, for some tumors (e.g., small apical tumors, posteriorly positioned tumors close to the diaphragm, and tumors close to the scapula) it may be difficult to accurately place the probe percutaneously. Patients with these types of tumors are more optimally treated with SRS. SRS with a high BED appears to be an effective modality for patients who are not operable candidates. As a result of the increased toxicity of a 60-Gy dose (in three fractions) for central tumors, a modified dose schema with a lower dose is required for patients with central tumors. We use a dose of 60 Gy in three fractions for peripheral lesions, and we use a modified dose schema with 48 Gy in four fractions for central tumors. In certain circumstances, a combined approach (RFA and SRS) may be beneficial.

Experience with MWA and cryotherapy is currently too limited to assess its value in the armamentarium against lung cancer; further investigations are ongoing.

MWA treatment times and heat-sink effect may be less with respect to RFA. This may prove to be protective, minimizing the necrosis of large blood vessels and reducing the risk of fatal hemoptysis. Future studies need to address long-term outcomes using standardized assessments of treatment response between centers. Comparisons among different RFA and SRS systems must be undertaken to delineate the optimal use of these strategies in the treatment of early-stage lung cancer. Until long-term data with these ablative techniques become available, surgical resection should be performed when clinically possible.

Although surgical resection remains the gold standard for local control of pulmonary malignancies, newer technologies such as RFA and SRS hold the potential for less invasive treatment in the future. We anticipate that these newer, less invasive techniques will complement existing minimally invasive surgical treatments, which may further ease the burden of treatment and ultimately improve the survival in selected high-risk patients with pulmonary tumors. Critical appraisal of these techniques over the next decade will establish their role, and the thoracic surgical oncologist must remain abreast of the evolving technology, playing an active leadership role in its evaluation.

AORTA

PULMONARY TRUNK AND BRANCH PULMONARY ARTERIES

CORONARY ARTERIES AND VEINS

In this chapter, we provide a brief overview of cardiac structure as it is relevant for the cardiac surgeon. We describe the heart as it is located in the body in its anatomic, or attitudinally correct, position.¹ Whenever possible, however, we illustrate the cardiac components as they would be viewed by the surgeon during an operative procedure, whether the pictures were taken in the operating room or are of anatomic specimens.² In some instances, information is best presented with the heart photographed in a nonsurgical orientation. When this occurs, it is clearly stated.

LOCATION OF THE HEART

Regardless of the surgical approach, the surgeon who enters the mediastinum is confronted by the heart enclosed in its pericardial sac. The sac is freestanding around the atrial chambers and the ventricles, but it becomes adherent to the adventitial coverings of the great arteries and veins at their entrances to and exits from the heart, where these attachments close the pericardial cavity. The pericardial cavity is contained between the two layers of the serous pericardium, a thin-walled sac folded on itself within the fibrous cavity. The inner layer, or epicardium, is firmly attached to the myocardium, whereas the outer layer is adherent to the fibrous pericardium. The pericardial cavity, therefore, is the space between the inner lining of the fibrous pericardium and the surface of the heart (Fig. 47-1). By virtue of the shape of the cardiac chambers and the great arteries, there are two recesses within this cavity that are lined by serous pericardium. The first is the transverse sinus, a horseshoe-shaped space behind the great arteries and in front of the atria (Fig. 47-2). Laterally on each side, the ends of the transverse sinus are in free communication

with the rest of the pericardial cavity. The second pericardial recess is the oblique sinus, a blind-ending cavity behind the left atrium (Fig. 47-3).

Most of the cardiac surface facing the surgeon is occupied by the so-called right heart, which in reality is anterior. Thus, the surgeon is confronted by the extensive appendage of the right atrium, receiving the superior caval vein at its superior border. To the left are the aorta and the pulmonary trunk, exiting from the base of the heart and extending in a superior direction, with the aortic root in an inferior and rightward position. When the aortic root is not in this “normal” relationship, the ventriculoarterial connections are almost always abnormal. The morphologically right appendage has a characteristic shape, being triangular and possessing a broad junction with its venous component (Fig. 47-4). The morphologically left appendage might not be seen immediately. If searched for, it is found as a tubular, meandering structure at the left border of the pulmonary trunk (Fig. 47-5), having a narrow junction with the rest of the atrium.

The ventricular mass then extends to the cardiac apex, which normally reaches into the left hemithorax. The overall cardiac silhouette is usually positioned with one third of its bulk to the right and two thirds to the left of the midline (Fig. 47-6). An anomalous position of either the ventricular mass or the apex is highly suggestive of the presence of congenital cardiac malformations, although not always. In shape, the ventricular mass is a three-sided pyramid, having (1) diaphragmatic, (2) anterior or sternocostal, and (3) left or pulmonary surfaces. The margin between the first two surfaces is sharp; therefore, it is called the acute margin. The transition between the sternocostal and pulmonary surfaces is more gradual and rounded. For the surgeon, it is the pulmonary surface that is considered to be the obtuse margin, as it is irrigated by the obtuse marginal arteries (Fig. 47-7). The greater part of the anterior surface of the ventricular mass

[†]Deceased.

FIGURE 47-1 ■ The heart is shown as seen by the surgeon through a median sternotomy. The pericardial cavity has been opened and is between the fibrous pericardium and the epicardium. The compass shows the orientation. *Inf.*, Inferior; *Sup.*, superior. (Copyright for the original illustration from which this figure was prepared belongs to Benson R. Wilcox, Andrew C. Cook, and Robert H. Anderson.)

FIGURE 47-2 ■ With the pericardium opened in the operating room, the surgical clamp has been passed through the transverse sinus of the pericardium, which is between the back of the arterial trunks and the front of the atrial chambers. *Inf.*, Inferior; *Sup.*, superior. (Copyright for the original illustration from which this figure was prepared belongs to Benson R. Wilcox, Andrew C. Cook, and Robert H. Anderson.)

is occupied by the morphologically right ventricle. Its left border is marked by the anterior interventricular, or descending, branch of the left coronary artery, and its right border is marked by the right coronary artery, which runs obliquely in the atrioventricular groove.

Appreciating the surface anatomy of the heart is helpful in determining the most appropriate site for an incision to gain access to a given cardiac chamber.² For example, the relatively bloodless outlet portion of the right ventricle just beneath the origin of the pulmonary trunk affords ready access to the ventricular cavity. The important landmark for the right atrium is the terminal groove, or sulcus terminalis, which marks the border

FIGURE 47-3 ■ This anatomic specimen has been removed from the body and is viewed from behind, with the apex pointing downward. The oblique sinus of the pericardium is seen between the pericardial reflections around the pulmonary veins and the inferior caval vein. *Inf.*, Inferior; *Sup.*, superior. (Copyright for the original illustration from which this figure was prepared belongs to Benson R. Wilcox, Andrew C. Cook, and Robert H. Anderson.)

FIGURE 47-4 ■ This picture of the heart, as seen in the operating room through a median sternotomy, shows the typical triangular appearance of the morphologically right atrial appendage. *Inf.*, Inferior; *Sup.*, superior. (Copyright for the original illustration from which this figure was prepared belongs to Benson R. Wilcox, Andrew C. Cook, and Robert H. Anderson.)

between the appendage and the venous component (Fig. 47-8). The sinus node is typically located in this groove, usually laterally in the superior cavoatrial junction inferior to the crest of the appendage. Posterior and parallel to the terminal groove is a second, deeper groove between

FIGURE 47-5 ■ With the pericardium opened through a median sternotomy, the heart is rotated slightly to show the typical tubular configuration of the morphologically left atrial appendage. *Inf.*, Inferior; *RVOT*, right ventricular outflow tract; *Sup.*, superior. (Copyright for the original illustration from which this figure was prepared belongs to Benson R. Wilcox, Andrew C. Cook, and Robert H. Anderson.)

FIGURE 47-6 ■ The cardiac structure placed in the context of the chest as would be seen by a surgeon standing on the right side of the operating table. Note that in the usual situation, two thirds of the cardiac silhouette are positioned to the left of the midline. *Inf.*, Inferior; *Sup.*, superior. (Copyright for the original diagram from which this figure was prepared belongs to Benson R. Wilcox, Andrew C. Cook, and Robert H. Anderson.)

the right atrium and the right pulmonary veins. Dissections into this deep interatrial groove, also known as Waterston or Sondergaard groove, permit incisions to be made into the left atrium (Fig. 47-9).

MORPHOLOGICALLY RIGHT ATRIUM

The right atrium has three components: the appendage, the venous sinus receiving the systemic venous return, and the vestibule. It is separated from the left atrium by the septum. As mentioned, the junction between the

FIGURE 47-7 ■ This heart has been removed from the thorax and is viewed from the apex, looking toward the base of the ventricular mass. It shows the surfaces of the ventricular mass and the locations of the acute and obtuse margins. *Ant.*, Anterior, *Inf.*, inferior; *Post.*, posterior; *Sup.*, superior. (Copyright for the original illustration from which this figure was prepared belongs to Benson R. Wilcox, Andrew C. Cook, and Robert H. Anderson.)

FIGURE 47-8 ■ In this picture, taken in the operating room, the surgeon has reflected the atrial appendage to show the location of the terminal groove and the crest of the appendage. Note the site of the sinus node (*dotted lines*). *Inf.*, Inferior; *Sup.*, superior. (Copyright for the original illustration from which this figure was prepared belongs to Benson R. Wilcox, Andrew C. Cook, and Robert H. Anderson.)

appendage and the venous sinus is marked externally by the prominent terminal groove. Internally, the groove corresponds with the position of the terminal crest (*crista terminalis*), which gives origin to the pectinate muscles of the appendage (Fig. 47-10). Significantly, the pectinate muscles within the appendage encircle the full extent of the third component, the vestibule, which is the smooth muscle encircling the orifice of the tricuspid valve (Fig. 47-11). This extensive array of pectinate muscles serves to identify an atrium as being morphologically right even when abnormally located, or when duplicated as seen in isomerism.³ Superiorly and anteriorly, the appendage terminates in a prominent crest that forms the summit of the terminal groove and continues in the transverse sinus behind the aorta across the interatrial groove as Bachmann bundle (Fig. 47-12). The sinus node lies in the terminal groove in an immediately subepicardial position. It is a spindle-shaped structure that usually lies to

FIGURE 47-9 ■ In this view through a median sternotomy, the surgeon has incised through the epicardium covering Waterston groove, showing the base of the deep fold between the systemic venous tributaries and the right pulmonary veins. *Ant.*, Anterior; *Inf.*, inferior; *Post.*, posterior; *Sup.*, superior. the right of the crest—that is, lateral to the superior cavoatrial junction. In approximately one tenth of cases, the node extends across the crest into the interatrial groove, draping itself across the cavoatrial junction in horseshoe fashion.⁴ For the surgeon, the artery to the sinus node is also of significance. It is a branch of the right coronary artery in approximately 55% of individuals and a branch of the circumflex artery in the remainder.⁵ Regardless of its origin, it usually courses through the anterior interatrial groove toward the superior cavoatrial junction, frequently running within the atrial myocardium. Having reached the cavoatrial junction, the artery may cross the crest of the appendage, course

FIGURE 47-11 ■ The right atrium has been opened to show the smooth vestibule of the tricuspid valve. The three leaflets of the valve are positioned septally, anterosuperiorly, and inferiorly. Note the extensive subthebesian sinus, often described as subeustachian when the heart is viewed in attitudinally incorrect fashion. *Ant.*, Anterior; *Inf.*, inferior; *Post.*, posterior; *Sup.*, superior. retrocavally, or even divide to form an arterial circle around the junction.

On first sight, when inspecting the internal morphology of the right atrium, there appears to be an extensive septal surface between the orifices of the caval veins and the orifice of the tricuspid valve. The apparent extent of this septum is spurious.^{6,7} The true septum between the right and left atrial chambers is formed by the floor of the oval fossa (derived from the fetal flap valve), and its adjacent anteroinferior muscular rim.⁶ The extensive superior rim, or the so-called septum secundum, is formed by a deep interatrial fold extending between the systemic and the pulmonary veins (Fig. 47-13). The larger part of the anterior atrial wall is folded around the aortic root. That the margins of the true atrial septum

FIGURE 47-13 ■ This heart has been sectioned in four-chamber fashion through the oval fossa. The section shows that the so-called septum secundum is no more than the infolded atrial walls between the tributaries of the systemic venous sinus and the right pulmonary veins. The true septal structures are the floor of the oval fossa (flap valve) and its hinge point from the antero-inferior rim. *Inf.*, Inferior; *L*, left; *R*, right; *Sup.*, superior. are limited is of major surgical importance, as it is easy to pass outside the heart when attempting to gain access to the left atrium through a right atrial approach.

In addition to the position of the sinus node, and the extent of the atrial septum, the other major area of surgical significance in the right atrium is the site of the atrioventricular node. This is contained within the triangle of Koch (Fig. 47-14). This important landmark is demarcated by the tendon of Todaro, the attachment of the septal leaflet of the tricuspid valve, and the orifice of the coronary sinus.⁸ The tendon of Todaro is a fibrous structure formed by the union of the eustachian and thebesian valves. The fibrous extension of these two valvar remnants buries itself in the tissue separating the oval fossa from the mouth of the coronary sinus, and it runs medially as the tendon of Todaro, which inserts into the central fibrous body. The entire atrial component of the axis of atrioventricular conduction tissues is contained within the confines of the triangle of Koch. If, in hearts with normal segmental connections, this area is scrupulously avoided during surgical procedures, the atrioventricular conduction tissues will not be damaged. The node itself, located in the smooth atrial musculature of the triangle, is some distance above the hinge point of

FIGURE 47-14 ■ The right atrium has been opened through a median sternotomy to show the landmarks of the triangle of Koch. In this patient, the continuation of the eustachian valve through the tendon of Todaro is clearly seen, with the tendon inserting into the atrioventricular component of the central fibrous body. *Inf.*, Inferior; *Sup.*, superior; *TV*, tricuspid valve. the septal leaflet of the tricuspid valve. The atrioventricular bundle, however, penetrates more or less directly at the apex of the triangle of Koch.

Much has been written in recent years about the role of “specialized” pathways of tissue in conduction of the sinus impulse to the atrioventricular node.^{9,10} It can now be stated with certainty that there are no insulated or isolated tracts of specialized conduction tissue extending between the nodes that can be avoided surgically, as is possible with the penetrating and branching atrioventricular bundles.¹¹ The major muscle bundles of the atrial chambers serve as preferential pathways of conduction, but the course of these preferential pathways is dictated by the overall geometry of the chambers. Ideally, prominent muscle bundles, such as the terminal crest or the superior rim of the oval fossa, should be preserved during atrial surgery. But even if they cannot be preserved, the surgeon can be sure that internodal conduction will continue as long as some strand of atrial myocardium connects the nodes, provided that the arterial supply to the nodes, or the nodes themselves, are not traumatized. The key to avoidance of postoperative atrial arrhythmias, therefore, is the fastidious preservation of the sinus and atrioventricular nodes and their arteries.²

The central fibrous body touches on three of the four cardiac chambers, but it is in the right atrium that it becomes first, and perhaps most clearly, evident to the surgeon (see Fig. 47-14). Rather than being a specific body, it is better conceptualized as an area in the heart where the membranous septum and the leaflets of the atrioventricular and aortic valves join in fibrous continuity. When viewed from the left heart (Fig. 47-15), it is possible to assess its proximity to the aortic and mitral valves and to the left bundle branch of the conduction axis. Because of this intimate relationship to so many important structures in the heart, the central fibrous body acts as an anatomic focal point for the cardiac surgeon.²

FIGURE 47-15 ■ The left ventricular aspect of the aortic root, illustrating the various components of the fibrous skeleton. The area of fibrous continuity between the leaflets of the aortic and mitral valves is thickened at both ends to form the so-called fibrous trigones. As can be seen, the right trigone is then continuous with the membranous septum, with these structures forming the central fibrous body. Note that the membranous septum itself continues upward to the sinotubular junction as one of the fibrous interleaflet triangles of the aortic root. Note also the location of the left bundle branch (see Fig. 47-26). *L*, Left; *R*, right. (Copyright for the original diagram from which this figure was prepared belongs to Benson R. Wilcox, Andrew C. Cook, and Robert H. Anderson.)

The vestibule of the atrium, surrounding the orifice of the tricuspid valve, is continuous with both the venous component and the appendage of the right atrium. Its anterosuperior part overlies the anteroseptal commissure of the tricuspid valve and continues along the supraventricular crest of the right ventricle. The posteroinferior component extends beneath the orifice of the coronary sinus, where there is usually an extensive trabeculated diverticulum found behind the sinus, the so-called post-eustachian sinus of Keith.

MORPHOLOGICALLY LEFT ATRIUM

Because of its position, only the appendage of the left atrium may be immediately evident to a surgeon upon exposing the heart. Like the right atrium, the left atrium has a venous component, an appendage, and a vestibule, and it is separated from its partner by the septum. In addition, the left atrium possesses a well-formed body, forming the dome of the atrium when the veins are connected anomalously, as in totally anomalous pulmonary venous connection. Unlike that of the right atrium, however, the venous component of the left atrium is considerably larger than the appendage, and the narrow junction between these two parts is not marked by either a terminal groove or a crest (Fig. 47-16). The pectinate muscles are confined within the appendage, and again, unlike on the right side, they do not extend around the vestibule.³ This difference in the extent of the pectinate muscles always permits the morphologically right appendage to be distinguished from the morphologically left structure. Because of its posterior position and its firm anchorage by the four pulmonary veins, direct access to the left atrium can be difficult; therefore, surgeons must use their knowledge of anatomy to gain the best exposure of the cavity. Probably the most popular route is an

FIGURE 47-16 ■ The morphologically left atrium is photographed from its left side to show the component parts. Note the extensive body, which also receives the septal aspect of the chamber. (Copyright for the original illustration from which this figure was prepared belongs to Benson R. Wilcox, Andrew C. Cook, and Robert H. Anderson.)

incision made just posterior to the interatrial groove. As described, this extensive infolding between the right pulmonary veins and the systemic veins produces the superior rim of the oval fossa. A posteriorly directed incision along this groove takes the surgeon directly into the left atrium. Because the infolding of the interatrial groove also forms the superior border of the oval fossa, much the same access can be gained by approaching through the

FIGURE 47-17 ■ The left atrium is photographed in the operating room through an incision made in the dome. Note the vestibule of the mitral valve, which has aortic and mural leaflets. *Ant.*, Anterior; *Inf.*, inferior; *Post.*, posterior; *Sup.*, superior. (Copyright for the original illustration from which this figure was prepared belongs to Benson R. Wilcox, Andrew C. Cook, and Robert H. Anderson.)

right atrium and incising just superiorly within the fossa. A further approach to the left atrium is the so-called superior approach, incising directly through the roof.

Once access is gained to the left atrium, the small size of the opening of the appendage is apparent, lying to the left of the mitral orifice as viewed by the surgeon. The greater part of the pulmonary venous atrium is usually located inferiorly, away from the operative field, and the vestibule of the mitral orifice dominates the picture (Fig. 47-17). The septal aspect is anterior, exhibiting the typically roughened flap-valve aspect of its left side (see Fig. 47-16). The large sweep of tissue between the flap-valve of the septum and the opening of the appendage is the internal aspect of the deep anterior interatrial groove.

MORPHOLOGICALLY RIGHT VENTRICLE

Understanding of ventricular morphology is greatly aided by considering the ventricles in terms of three components (Fig. 47-18), rather than in terms of the traditional sinus and conus parts.¹² The inlet portion of the right ventricle contains, and is limited by, the tricuspid valve and its tension apparatus. The leaflets of the valve are positioned septally, inferiorly (or murally), and anterosuperiorly. The most constant distinguishing feature of the valve is the direct attachments to the septum of the cords of its septal leaflet (Fig. 47-19). The trabecular component of the right ventricle extends out to the apex, where its wall is particularly thin and is especially vulnerable to perforation by cardiac catheters and pacemaker electrodes. The outlet component of the right ventricle is a complete muscular structure, the infundibulum, which supports the pulmonary valve. The three leaflets of the pulmonary valve do not have a ring or an annulus. Instead, they are attached to the infundibular musculature in semilunar fashion (Fig. 47-20), the semilunar hinge-points crossing the anatomic ventriculoarterial junction, which does form a complete ring, as does

FIGURE 47-18 ■ The morphologically right ventricle is opened in a clamlike fashion and the septal surface is photographed to show its three component parts. (Copyright for the original illustration from which this figure was prepared belongs to Benson R. Wilcox, Andrew C. Cook, and Robert H. Anderson.)

FIGURE 47-19 ■ The tricuspid valve is seen through the right atrium in the operating room. Note the tendinous cords that attach the septal leaflet directly to the septum. This is the most characteristic morphologic feature of the tricuspid valve. *Inf.*, Inferior; *Sup.*, superior. (Copyright for the original illustration from which this figure was prepared belongs to Benson R. Wilcox, Andrew C. Cook, and Robert H. Anderson.)

the sinotubular junction.¹³ The basal attachments of the leaflets are attached in the ventricle, upstream relative to the anatomic ventriculoarterial junction, whereas the peripheral attachments are to the arterial sinotubular junction. The overall valvar structure, therefore, takes the form of a three-pointed coronet (Fig. 47-21).

A distinguishing feature of the right ventricle is the prominent muscular shelf separating the tricuspid and pulmonary valves: the supraventricular crest. Although at first sight it looks like a large muscle bundle, much of the

FIGURE 47-20 ■ The pulmonary outflow tract has been opened, and the leaflets of the pulmonary valve have been removed, showing their initial semilunar attachment. The most distal attachment is to the sinotubular junction (*dotted line*). Proximally, the hinge point incorporates right ventricular musculature into the base of each pulmonary valvar sinus (*gray crescents*). Fibrous triangles composing the wall of the pulmonary trunk (*red triangles*) are incorporated into the ventricular outflow tract. (Copyright for the original illustration from which this figure was prepared belongs to Benson R. Wilcox, Andrew C. Cook, and Robert H. Anderson.)

FIGURE 47-21 ■ The idealized three-dimensional arrangement of the arterial valves. There is no ringlike annulus supporting the valvar leaflets. Instead, the leaflets are attached within the arterial root in crownlike fashion. (Copyright for the original diagram from which this figure was prepared belongs to Robert H. Anderson, Benson R. Wilcox, and Andrew C. Cook.)

crest is no more than the infolded inner heart curve. Incisions, or deep sutures through this part, run into the transverse sinus and right atrioventricular groove and can jeopardize the right coronary artery.¹⁴ The distal part of the crest is continuous with the freestanding subpulmonary infundibulum, the presence of this muscular sleeve permitting the valve to be removed and used as an autograft in the Ross procedure (Fig. 47-22). The body of the supraventricular crest inserts between the limbs of a prominent and important right ventricular septal trabeculation. This structure, called the *septomarginal trabeculation*, has superior and inferior limbs that clasp the crest. The superior limb runs up to the attachment of the

FIGURE 47-22 ■ The freestanding sleeve of subpulmonary infundibular musculature has been removed in this anatomic specimen, as the surgeon would remove the pulmonary valve during the Ross procedure. The dissection has not impinged on the cavity of the left ventricle. Note the location of the medial papillary muscle and the first septal perforating artery. (Copyright for the original illustration from which this figure was prepared belongs to Benson R. Wilcox, Andrew C. Cook, and Robert H. Anderson.)

leaflets of the pulmonary valve, whereas the inferior limb extends backward inferior to the interventricular component of the membranous septum. The characteristic medial papillary muscle (see Fig. 47-22) usually arises from this inferior limb, and a line extending from the muscle to the apex of the triangle of Koch marks the location of the atrioventricular conduction axis. The body of the septomarginal trabeculation runs to the apex of the ventricle, where it breaks up into a sheath of smaller trabeculations. Some of these mingle into the trabecular portion, and some support the tension apparatus of the tricuspid valve. Two trabeculations may be particularly prominent. One becomes the anterior papillary muscle of the tricuspid valve, and the other extends from the septomarginal trabeculation to the papillary muscle, forming the moderator band. Other significant right ventricular trabeculations are usually found in the transitional zone to the infundibulum. Variable in number, these are the septoparietal trabeculations (Fig. 47-23).

It is the coarseness of the apical trabeculations that is the most constant feature of the morphologically right ventricle when the chamber is malformed. In the normal heart, a number of morphologic differences exist between the two ventricles, including the arrangement of the leaflets of the atrioventricular valves and their tension apparatus, their shape, the thickness of their walls, and the configuration of the outflow tracts. These features, however, can be altered or lacking in the congenitally abnormal heart. When making the final arbitration, therefore, it is important to follow the “morphological method” introduced by Van Praagh and colleagues,¹⁵ which states that one variable feature should not be defined on the basis of another feature that is itself variable. When distinguishing ventricular morphology, therefore, it is necessary to rely on the contrast between
